Methods: We conducted a retrospective study including 146 patients who had their first PD catheter implanted between 1st of August 2012 and 31st of July 2022 in our institution. The primary endpoint was PD catheter failure, defined as removal of the PD catheter due to catheter-related complications. Kaplan-Meier curves were used to estimate catheter survival. Cox regression model was used to identify factors that were independently associated with catheter survival. All demographic and clinical characteristics of the patients and PD complications were included as covariates. A p value of less than 0.05 was considered statistically significant.

Results: The study population included 85 men and 61 women, aged 55.1 ± 16.7 years. Mean follow-up was 26.5 +/- 22.7 months. Diabetes was the most common etiology of the stage 5 chronic kidney disease (n = 41, 28%), followed by chronic glomerulonephritis (n = 30, 20.5%). Ninety patients (61.2%) had one or more comorbidities and seventeen (11.6%) had previous abdominal surgery. In 98 patients (60.1%), the PDC was inserted using a mini-laparotomy approach, whereas the laparoscopic method was used in 54 patients (33.1%).

Only 8 patients (4.9%) had their catheter placed percutaneously using the Seldinger technique. The total number of patients with one or more PD-related infectious complications during follow-up was 99 (67%): 51 patients (31%) had a single episode and 29 (17.8%) had multiple episodes of peritonitis; 34 patients (20.9%) had a single episode of PD catheter related exit site or tunnel infection, while 47 (28.8%) had more than 1 event. Sixty-six patients (45%) had PD-related mechanical complications, mostly due to outflow failure (19 patients with catheter migration, 11 with omental wrapping). The remaining non-infectious complications were hernia (n = 20, 13.7%), hemoperitoneum (n = 8, 5.5%), leakage (n = 4, 2.7%) and pleuroperitoneal shunt (n = 4, 2.7%).

Fourteen patients required intervention due to mechanical complications, namely repositioning of the catheter with fluoroscopic technique in 8 patients and surgical repositioning in 6. Removal of the catheter was required in 49 patients (33.6%). The leading cause of catheter removal was infection (n = 29, 59%): peritonitis in 28 patients and refractory tunnel infection in 1. Medical complications were also a significant factor, accounting for 40.8% of the removals (n = 20). Overall PD catheter survival rates over 12, 24 and 36 months were 80.2%, 72.4% and 61.6%, respectively. PD catheter-related non-infectious complications was the only independent variable significantly associated with catheter survival (Hazard ratio 2.573; 95% CI 1.426–4.645).

No significant association was observed between the PD catheter survival and other risk factors including age, diabetic status, comorbidities, previous abdominal surgeries, method of catheter insertion or infectious complications.

Conclusions: PDC non-infectious complications were the only independent factor significantly associated with catheter survival. Despite the significant number of infectious complications, including peritonitis, it was found that these complications did not result in a significant decrease in catheter survival. These findings highlight the crucial role of proper management of peritoneal dialysis catheter-related non-infectious complications for successful and long-term usage of PDC.

Figure 1: Kaplan-Meier curves for catheter longevity in patients with (green) and without (blue) peritoneal dialysis catheter related non-infectious complications.
Results: Techniquesurvival. (mechanical and infectious) within 90 days. Secondary outcomes included PD-L catheter placement. The primary outcomes were early complications whether the catheter was used during the first 15 days (PD-E) or 15 days after to October 2015). The patients were divided into two groups according to all patients treated with peritoneal dialysis for 18 months (from April 2014 year and four-month period (from April 2014 to August 2021), including Among the 36 patients included in the study, 14 started PD early (38.8%), while 22 started it 15 days after catheter placement (61.2%). The mean age between the two groups was not significantly different (41 ± 17 years vs 35 ± 16 years, p: not significant). There were no significant differences in the Charlson comorbidity index or the degree of autonomy. The incidence of infections was not significantly different between the two groups (13.6% in PD-L vs 21.4% in PD-E, p: not significant). The total number of mechanical complications was not significantly higher in the PD-E group compared to the PD-L group (42.8% vs 27.3%, respectively, p: not significant). Kaplan-Meier estimates of technique survival were comparable between the groups (log Rank: 1.908, p: 0.67). Our study showed no increase in the risk of complications associated with early use of the PD catheter and no difference in technique survival. PD can be used as first-line renal replacement therapy in the unplanned initiation of chronic dialysis.

Conclusion: Our study showed no increase in the risk of complications associated with early use of the PD catheter and no difference in technique survival. PD can be used as first-line renal replacement therapy in the unplanned initiation of chronic dialysis.

"HOME-MADE" REMOTE MANAGEMENT IN CAPD
Silvio Di Stante, Laurentia Lionte, Lucia Lucarelli, Loredana Magi, Sabrina Mambelli, Elena Manfredi, Elisa Mazzoli, Alessandra Ranocchi, Giovanni D’Onofrio, Angela Pia Rinaldi, Antonella Sebastianelli, Stefania Silvestrini and Marina Di Luca
UOC Nephrology and Dialysis, Azienda Ospedaliera “Ospedali Riuniti Marche Nord”, Fano, Italy

Background and Aims: Remote control of dialysis parameters has become an essential routine in the Centers that perform Peritoneal Dialysis. For patients in APD there are Cloud-based platforms or with VPN connection that allow daily monitoring and which have proved to be very useful for reducing hospital visits and treatment complications, especially during the recent pandemic. The same cannot be said of CAPD patients for whom the procedures are carried out manually, without electromedical devices, with a paper report of the parameters. Furthermore, to date, there are no dedicated applications able to communicate these important measurements to the Centres.

Method: In March 2021 we created a calculation table file, with limited data entry, divided by days, daily exchanges and monthly sheets. Patients and/or caregivers can insert loading and drainage volumes, type of bags used, blood pressure values, weight and diuresis at an agreed time. The system automatically calculates and graphically displays the total daily and monthly average ultrafiltration for each exchange, the daily balance as well as the average of all the aforementioned parameters for the entered period (Figure 1). There is also a graphic sheet with an annual summary of the average values (Figure 2). The file is uploaded online, subject to the patient’s consent, via a free file hosting service that allows modification and reading shared and protected by password between patients and Center operators.

Results: To date, 9 CAPD patients in our Center have been included in the program with good acceptance by patients and caregivers, who enter data based on their availability of time and regularly in anticipation of the monthly outpatient visit. The staff of the Centre, both Doctors and Nursing, access the file periodically, in case of need and in preparation for the visit. In this way, regular checks and evaluations of prescription compliance, ultrafiltration efficacy, maintenance within the expected ranges of weight, blood pressure and fluid balance of patients in CAPD are obtained, as is the case for patients in APD.

Conclusion: The creation of a shared file for monitoring the dialysis parameters of CAPD patients could be able to reduce the existing gap with those in APD, at least as regards the vital and dialysis parameters, since the functioning of the catheter in individual exchanges cannot be evaluated. A more extensive experience is needed, and is being studied, to confirm the usefulness of this approach which currently already guarantees a reduction in hospital admissions and integrates and structures the clinical information that can be obtained in the traditional way.
Figure 1:
Background and Aims: The evidence on the management of renal anaemia in peritoneal dialysis (PD) is much weaker than in hemodialysis (HD). Current guidelines establish the same haemoglobin (Hb) target for patients under erythropoietin stimulating agents (ESAs) in both dialysis techniques (PD, HD), although patients in PD are usually younger, more active and less comorbid. Unfortunately, there is not randomized controlled trials evaluating the efficacy and safety the effect of different Hb target on clinical outcomes. The aim of this study is to describe the current situation of anaemia prevalence, treatments, and achievement of clinical guidelines recommendations in this population.

Method: Retrospective nationwide multicenter study including patients from 19 PD units. All prevalent PD patients that were active in the technique in November 2019 for at least 3 months was included (to avoid COVID pandemic interferences). Exclusion criteria were a previous kidney transplant failure and being on PD due to a cardio-renal syndrome with a residual renal function over 20 ml/min/1.73 m². The nephrologists collected baseline data, demographics, comorbidities, and data related to anaemia management (ie, laboratory values, previously prescribed treatments, and subsequent adjustments) from electronic medical records. The European adaptation of KDIGO guidelines was the reference for iron and Hb limits, prescriptions and targets.

Results: A total of 343 patients (mean age 62.9 years, 61.2% male) were included. Regarding anaemia treatment prescription, 72.9% were receiving ESAs and 33.2% iron therapy (20.7% intravenously-IV and 12.5% orally). Eighty-two (32.8%) patients were receiving ESA without iron therapy, despite having an indication to do it according ERBP guidelines in 53 out of them. After knowing lab results, iron therapy was only started in 8 (15%) patients. Among ESA-treated patients, 58.8% had a normal control (Hb 10–12 g/dl). Seventeen patients had haemoglobin over 13 g/dl, and 12 of them continued receiving ESA after knowing lab results. Only three patients had persistent haemoglobin <10 g/dl. Seventy patients (2%) met criteria for ESA resistance (epoetin dose >300 IU/kg/week). Patients in the highest tertile of erythropoietin resistance index (ERI) (>6.3 UI/kg/week/g/dl) were more inflamed, had lower albumin levels and lower residual renal function.

Conclusion: Anaemia prevalence is high in this population and its management in PD Units could be improved according to the ERBP guidelines. The lack of iron therapy in patients who should have received it and the excessive tolerance to high Hb levels are the most relevant opportunities to improve compliance with clinical guidelines.

INNOVATIVE ARTIFICIAL INTELLIGENCE EDUCATION TOOL IN PERITONEAL DIALYSIS PATIENTS

Woo-jean Lin1, Ching-I Cheng2, Jui-Hsin Hsu1, Hui-Ting Liu1, Yi-Tingchen2, Yu-Hsiang Chou3 and Chih-Kang Chiang2

Abstract

Background and Aims: Home self-care is an essential part of peritoneal dialysis. Adequate home self-care ability and how to prevent infection complication is very important for patients with PD. National Taiwan University Hospital peritoneal dialysis center began to introduce AI (artificial intelligence) health education tool-PD chatbot since May 2021. This chatbot can automatically reply and has a variety of interactive games. We used chatbot to educate patients how to deal with peritonitis and catheter-related infections. Using these interactive games could enhance patients’ understanding and help them to review the principles of peritoneal dialysis exchange and exit site care skills. Using chatbot, we could predict infection risks according to the patient’s adherence and make patients understand the possible risks and probability of non-compliance to achieve the purpose of strengthening cognition.

Method: We designed interactive games “Predict Peritonitis Risk” and “Predict Exit site Infection Risk”. The health education game was designed according to the expert experience and had been reviewed by 9 experts with practical experience in patients with hemodialysis and peritoneal dialysis, including 1 nephrologist and 8 senior dialysis nurses. We used technical evaluation form for training patients’ standard of peritoneal dialysis center. The user interface of the chatbot was designed based on the PD patients’ habits of dialysate exchange and exit site care. Through the interactive games and prediction of risks of infection, the patient was reminded of the key points of operating dialysate exchange and exit site care. It also could enhance self-care awareness and improve self-cognition and behavior. We utilized Likert 5-point score to investigate patients’ recognition of using interactive games and satisfaction.

Results: In November 2021, a total of 173 peritoneal dialysis patients were recruited. The percentage of male was 48%. Among these patients, 38.7% were 21–50 years old, 46.8% were 51–70 years old, and 10% did not comply with environmental preparations. Regarding the technical part of peritoneal dialysis exchange, 15% patients had the habit of occasional eating raw food, and 18% patients had constipation and diarrhea. In terms of the care of exit site, 21.4% patients did not watch out expired date of the medical materials, and 25% patients did not replace disinfection solution for more than 30 days. PD exit site infection risk notification and health education could correct patients’ poor habits at home. In 5-point scale, 90.8% patients scored more than 4 points about the item of “Overall Satisfaction with AI Interactive Games”.

Conclusion: Peritoneal dialysis is a long-term treatment. Through regular training and technical strengthening and reminders, the home exchange can be standardized and more reliable. Combining innovative AI health education with interactive games to educate peritonitis and catheter-related infections could allow patients to accept different health education models to improve learning and motivation of home care. As a result, techniques can be performed more accurate and standardized, and then we can reduce the infection-related complications of peritoneal dialysis.

PERITONEAL CLEARANCE OF TRACE ELEMENTS IN PERITONEAL DIALYSIS PATIENTS

Suleyman Koz1, Esin Oguz1,2 and Cagla Sayın1,2

Background and Aims: Both accumulations and deficiencies of trace elements (TE) could be seen in peritoneal dialysis (PD) patients. Peritoneal clearance remains major route of elimination for many solutes including TE, in PD patients. Imbalances of TE may have deleterious effects on the patients. Data on TE balances in PD patients are inadequate. Here, we present some data from a larger study. We aimed to analyze peritoneal clearance of Boron (B), Copper (Cu), Zinc (Zn), Selenium (Se), Strontium (Sr) and Molybdenum (Mo) in a cohort of PD patients.

Results: Data on plasma levels, clearances and daily loss of TE are shown in the Table 1. The clearances were ordered from smallest to largest as follows: Zn, Cu, Se, Sr, Mo, Ni, B. On the other hand, spent dialysate daily element losses were ordered from smallest to highest as follows: Cr, Ni, Se, Mo, Cu, Sr, Zn, B

Conclusion: Our study provides data on elimination of some trace elements, which may help to better understand the TE balance in PD patients. Data suggest that B has the highest and Zn the lowest peritoneal clearance values.

Conclusion: Peritoneal dialysis is a long-term treatment. Through regular training and technical strengthening and reminders, the home exchange can be standardized and more reliable. Combining innovative AI health education with interactive games to educate peritonitis and catheter-related infections could allow patients to accept different health education models to improve learning and motivation of home care. As a result, techniques can be performed more accurate and standardized, and then we can reduce the infection-related complications of peritoneal dialysis.
Background and Aims: Peritoneal dialysis (PD) is the incident kidney replacement therapy (KRT) for 16% of patients in Scotland. Conveying the healthcare-related burden associated with KRT is essential for informed patient choice but has not been characterised as comprehensively in PD as in haemodialysis (HD) or kidney transplantation. Knowledge of the patient journey and the cumulative impact of renal service interactions is key to practising patient-centred realistic medicine, and considering service configuration, resource deployment, and the targeting of carbon emission reductions necessary for addressing the climate emergency. This study therefore aimed to capture the nature and extent of kidney-related healthcare activity in the first year of PD therapy.

Method: This retrospective observational study included all incident adult patients on PD between 1st January 2015–31st December 2019 from two Scottish health boards servicing a population of 1.6 million people. Analysis was undertaken of prospectively recorded healthcare-related activity from the electronic patient record. Data pertaining to hospital admissions, scheduled and unscheduled outpatient clinic, and home visit activity was captured up to the first 365 days post commencement of PD, and censored by death or switch in KRT modality. Data concerning dialysis access activity, radiological activity and relevant infection episodes was also analysed. Carbon mapping of healthcare activity was estimated using patient postcode data and previously published carbon footprint estimations.

Results: PD was initiated in 112 patients over the study period. Four patients died and 63 patients (52%) transitioned to another KRT within 365 days of commencing PD (10 live donor kidney transplantation, 19 cadaveric kidney transplantation, 34 HD) and one patient recovered native function. The median duration from insertion of PD catheter to utilisation was 26 days (IQR 34). Mean distance travelled to renal unit was 23.7 miles. Over the first year, patients had a mean 36.4 days (SD 22.7) of face-to-face contact days with renal services. This included a mean of 1.5 (SD 1.6) hospital admissions, with a median 5 (IQR 10.8) in-patient days. Additionally, a mean of 2.5 (SD 2.5) unscheduled ambulatory assessments per patient; 4.7 (SD 6.2) telephone consultations; 14.9 (SD 8.96) face-to-face clinics with a PD nurse and 7 (SD 3.9) with a nephrologist, and 2.5 (SD 3.4) home visits occurred. Within these contact episodes there were on average 4.4 (SD 4.1) radiological investigations per patient (3.1 x-rays, 0.4 CTs, 0.4 ultrasounds, 0.1 MRIs); and 1.4 (SD 0.3) infection events (0.02 bloodstream infections, 0.2 urinary tract infections, 0.7 PD catheter site infections, and 0.5 PD peritonitis episodes). The estimated carbon footprint from patient contact with renal services was 803.6 kg CO2e/patient; this included 402.6 kg CO2e/patient for inpatient days, 54.6 kg CO2e/patient for unscheduled ambulatory assessment, 0.24 kg CO2e/patient for telephone consultations, 293.8 kg CO2e/patient for outpatient clinic activity and 17.6 kg CO2e/patient for home visits, and 34.8 kg CO2e/patient for radiological investigation and treatment of infection episodes.

Conclusion: Although PD is a home-based therapy patients should be aware of the frequency of attendance and admission days in the first year. KRT transition appeared common in this cohort, with similar proportions of transplantation and conversion to HD which prompts consideration of early vein mapping for arteriovenous haemodialysis in patients without prospect of early transplantation. Sixty-eight percent of the cohort experienced at least one infection episode necessitating anti-microbials, with implications for patient experience and anti-microbial stewardship. The length of time PD catheters remained in situ but not used was heterogeneous and merits further examination given the frequency of infection episodes and KRT transition. Estimates of carbon footprint relating to routine and unscheduled care indicate that carbon hotspots include patient travel and hospital admissions, and episodes of peritonitis; a full life cycle analysis is merited.

INFLUENCE OF DIETARY INTAKE ON GASTROINTESTINAL SYMPTOMS AND INFLAMMATION MARKERS IN PERITONEAL DIALYSIS PATIENTS IN SLOVENIA

Mia Majer1, Bojan Knap2,3 and Nada Rotovnik Kozjek1,3,4

1Institute of Oncology, Department of Clinical Nutrition, Ljubljana, Slovenia, 2University Medical Center Ljubljana, Department of Nephrology, Ljubljana, Slovenia, 3Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia and 4Faculty of Health Sciences Izola, University of Primorska, Izola, Slovenia

Background and Aims: Gastrointestinal symptoms are prevalent in patients with end-stage renal disease. Gastrointestinal symptoms in such patients are related to gastric hypomotility, increased medication intake, uremia, and changes in diet. In addition GI symptoms and problems associated with bowel dysfunction are a common cause of technique failure and poor dialysis efficacy. The reason for presence of some gastrointestinal symptoms is also chronic inflammatory state. Inflammation can have many negative effects, including decreased appetite, accelerated protein skeletal muscle breakdown and hypercatabolism.

Method: 14 peritoneal dialysis patients were included in single Department of Nephrology in the University Medical Center in Ljubljana. All patients were interviewed by a dietitian and nutritional assessment was conducted. Gastrointestinal symptom Rating Scale (GSRS) with 7-grade Likert scale was used to evaluate the intensity of GI symptoms and Bristol Stool Form Scale (BSFS) to classify patient’s stool. The dietary intake of peritoneal dialysis patients was assessed using 7-day food diaries and analyzed with Prodi program (PRODI® 6.4 Expert program, Stuttgart, Deutschland). Body composition has been measured with bio impedance spectroscopy. Routine blood analysis was performed.

Results: Among 14 patients undergoing peritoneal dialysis, most of them were male (71.4%) with average age of 53.07 ± 12.32 years. Average energy intake of 14 patients was 21.05 ± 5.72 kcal/kg body weight per day, average protein intake was 0.87 ± 0.39 g/ kg body weight per day and average fiber intake was 13.75 ± 7.25 g per day. They were inadequate according to the dietary guidelines for peritoneal dialysis patients. Average dietary protein-fiber index was 6.86 ± 3.81 per day. Average dietary potassium intake was 1917.80 ± 790.08 mg per day which corresponds to the guidelines for peritoneal dialysis patients and average potassium serum value 4.45 ± 0.42 mmol/L. GSRS questionnaire showed peritoneal patients had minor to mild discomfort in abdominal pain, constipation and indigestion GI symptom cluster. Patients’ self-analysis of stool showed BSFS Types 3.23 ± 1.64 if BSFS Types 3–5 are defined as normal stools. Dietary protein intake strongly correlated with dietary energy intake (r = 0.76,
p = 0.003), dietary protein-fiber index strongly correlated with PRAL value (r = 0.70, p = 0.007) and dietary potassium moderately to strongly correlated with dietary fiber intake (r = 0.62, p = 0.025). Serum value of IL-6 strongly correlated with dietary potassium intake (r = 0.72, p = 0.006) and moderately to strongly correlated with dietary fiber intake (r = 0.6, p = 0.034). The correlation between dietary potassium intake and serum hsCRP was significant (p = 0.042). The correlation between Bristol stool consistency value and serum hsCRP was significant (p = 0.0255). The correlation between total GSRS score and serum value of albumin was significant (p = 0.0015). The correlation between total GSRS score and dietary protein-fiber index was significant (p = 0.0403).

Conclusion: Gastrointestinal diseases in peritoneal dialysis patients are comparatively understudied in the literature, despite having a significant impact on dialysis efficacy and the quality of life. Analysis of GSRS questionnaire showed that abdominal pain, constipation and indigestion caused minor to mild discomfort in PD patients. The analysis also showed that fiber intake, potassium intake and gastrointestinal symptoms are significantly associated with inflammation markers and are important contributing factors to chronic inflammatory state in these patients. Patients still lack the basic knowledge of nutrition, thus in the future nutritional consultations, innovative teaching techniques and help will be crucial to prevent the decline in nutritional status.

#4797
ASSOCIATION BETWEEN BLOOD PRESSURE AND SALT CONSUMPTION WITH FLUID STATUS USING BIOIMPEDANCE SPECTROSCOPY IN PERITONEAL DIALYSIS PATIENTS
Rita Silva, Pedro Castro, Marina Sofia Rodrigues Reis, Sofia Cerqueira, Catarina Romãozinho, Pedro Maia, Teresa Mendes and Rui Alves
Coimbra University Hospital, Nephrology, Portugal

Background and Aims: Control of extracellular volume in peritoneal dialysis (PD) patients requires both removal of sodium and water. Hypervolemia occurs more frequently in PD patients and is associated with greater morbidity and mortality. Dietary salt restriction (Na+ < 2g) is recommended in all PD patients. Most patients do not comply with this recommendation (prevalence difficult to assess). Bioimpedance spectroscopy (BIS) devices can help assess volume overload in patients receiving maintenance PD. The aim of our study was to determine the association between fluid status as measured using BIS to BP and salt consumption in continuous ambulatory peritoneal dialysis (CAPD) patients.

Method: We performed a retrospective, longitudinal study, that included 60 PD patients followed at our unit. Demographic and clinical characteristics, such as age, gender, chronic kidney disease (CKD) etiology, time on PD program, dialytic efficacy (Kt/V), peritoneal equilibration test results, BIS results and episodes of peritonitis were registered from our unit database. We measured total sodium removal and estimated daily sodium intake using dietary recall for one day, during the assessment of dialysis adequacy. Based on a 2017 study of 87 patients on PD that sought a correlation between effective daily sodium intake (memory recollection) and urinary + peritoneal sodium sieving. It allowed, through logistic regression, the creation of equations for patients with and without renal residual function (RRF) (Pearson’s 0.6).

- RRF(-) group, sodium intake (mg/d) = 19.3 × peritoneal sodium removal (mEq/d) + 211
- RRF(+) group, sodium intake (mg/d) = 15.4 × total sodium removal (mEq/d) + 609

Statistical analyses were performed using SPSS statistics version 23.0. The statistical hypothesis tests with p-value <0.05 were considered significant.

Results: Sixty patients (male: 60%) with a mean age of 55.9 ± 13.7 years were selected. Observation time on dialysis was 24.8 months ± 11.9 (min. 2, max. 63). The most common etiology of CKD was glomerular diseases (n = 16, 26.7%), followed by uncertain etiology (n = 11, 18.3%) and diabetic kidney disease (n = 9, 15%). In total, 71.7% of patients were on continuous ambulatory peritoneal dialysis (CAPD). Mean Kt/V was 2.2 ± 0.6 and the majority of patients were high-average transporters. Previous comorbidities were arterial hypertension (n = 60, 100%), diabetes (n = 16, 26.7%), heart failure (n = 13, 21.7%), body mass index <30 kg/m2 (n = 22, 36.7%) and dyslipidemia (n = 40, 66.7%). According to European Society of Cardiology we define three stages of hypertension: stage 1 (140–159/90–99 mmHg) with 15 patients (25%), stage 2 (160–179/100–109 mmHg) with 14 patients (23.3%) and stage 3 (≥180/≥110 mmHg) with 4 patients (6.7%). In total, we have 27 patients (45%) with hypertension under control. A statistically significant positive correlation was found between a status of overhydration (≥2 liters) with salt consumption (Na+ > 2g) (p = 0.01) and also of hypertension stages 2 and 3 (p = 0.03).

Conclusion: In PD patients, BIS is a reliable method for evaluating volume status. We found that stable CAPD patients with uncontrolled BP had higher overhydration and salt consumption compared to patients whose BP was controlled. Control of hypervolemia and blood pressure is associated with better cardiac condition. Thus, it is important to encourage patients on peritoneal dialysis to significantly restrict salt intake.

#3122
30-DAY COMPLICATIONS IN PERITONEAL DIALYSIS CATHETERS INSERTED PERCUTANEOUSLY VERSUS SURGICALLY IN A SECOND LEVEL HOSPITAL IN MERIDA, YUCATAN, MEXICO
Leticia Tapia and Naomi Alvarez
General Hospital Agustin O’Horan, Nephrology, Mérida, Mexico

Background and Aims: Peritoneal dialysis (PD) catheter insertion technique has an impact on the health outcomes and technical success in PD. The percutaneous technique allows for a bedside, minimally invasive and faster insertion without the need of using an operating room and general anesthesia. In 2021, Agarwal et. al reported that percutaneous insertion was associated with a 64% relative risk reduction (RRR) of early exit site infection and a 48% RRR of early peritonitis with no difference in terms of mechanical complications compared to the surgical technique [1]. The aim of our study was to describe the frequency of mechanical and infectious complications within the first 30 days of PD catheter insertion between the percutaneous and surgical technique.

Method: We conducted a descriptive and prospective study in our Hospital from January 1st to December 31st, 2022. Patients who were candidates for renal replacement therapy with PD and who had no previous history of abdominal surgery or only minor abdominal surgery, underwent percutaneous insertion of PD catheter by a nephrologist with a bedside blind technique, whereas patients with previous abdominal surgery underwent surgical insertion with a mini laparotomy. Informed consent and preoperative blood tests were obtained before the procedure in both techniques. Patient preparation for the percutaneous insertion included fasting the night before, colonic enema and the placement of a urinary catheter, patients received antimicrobial prophylaxis as well as analgesia and light sedation. Mechanical and infectious complications within the first 30 days after insertion of double cuff Tenckhoff catheters were registered.

Results: During the study period, 155 PD catheter insertions took place in our hospital, the majority of insertions were surgical (53.5% versus 46.4%) and happened in women (60.6%). The mean age of the population was 51.5 years and 70.3% of the participants were diabetic. Exit-site infection was significantly more frequent in the surgically placed PD catheters (10% versus 1%, p = 0.02), there was a tendency for more mechanical dysfunction in the surgical placement catheters (10.8% versus 1.3%, p = 0.07) and transfer to hemodialysis was more frequent in the surgical insertion group (10.8% versus 1.3%, p = 0.01). There was no difference between peritonitis in both groups and the frequency of uncomplicated PD catheters (catheter survival without any complication) was similar in both techniques.

Conclusion: Bedside PD catheter insertion by the nephrologist using a percutaneous technique can be an easy, timely, safe and adequate procedure with comparable success to the surgical insertion. It may have the advantage of more efficient control of infectious and mechanical complications. PD catheter survival without any complication was similar in both techniques.

**PSYCHOLOGICAL CHALLENGES OF THE PATIENT STARTING PERITONEAL DIALYSIS**

Marica Mulé1, Vincenzo Terlizzi2, Diana Bertoni3, Carla Bussi1, Anna Bertoni3, Francesco Scolari1, Valerio Vizzardi1 and Federico Alberici1

1Division of Nephrology and Dialysis, ASST Spedali Civili, Medical and Surgical Specialties, Radiological Sciences, and Public Health, University of Brescia, Brescia, Italy and 2Psychology, Catholic University, Milan, Italy

**Background and Aims:** The start of peritoneal dialysis (PD) in patients affected by end stage renal disease (ESRD) may have a significant psychological impact. Aim of this study was to assess the most frequent reasons triggering the request of psychological referral in patients starting PD.

**Method:** A thematic analysis of the clinical diaries of the psychological support sessions of 15 consecutive patients requesting a psychological referral during the first 3 months of PD was performed from 2018 to 2021.

**Results:** Fifteen patients were enrolled, 6 women and 9 men. The median age was 59 (range 27–73) and the cause of the ESRD were glomerulonephritis (5/15), diabetic kidney disease (2/15), tubulo-interstitial (2/15), vascular nephropathy (1/15), other (5/15). The most frequent symptoms triggering the request for a psychological referral were insomnia and anxiety respectively in 12 and 15 cases. From the psychological assessments the most frequent causes of the patients’ symptoms have been identified as per follow:

- Difficulties in elaborating and accepting the chronic disease (why me?) in 15 Patients.
- Difficulties in accepting the esthetical impact of the peritoneal catheter in the summer how I do it? in 15 patients.
- The difficulties related to managing fluid restrictions in 15 patients.
- The limitations to traveling (what if something happens to me?) in 13 patients.
- The difficulties to comply to the dietetic restriction (things taste like cardboard; I always eat the same things) in 7 patients.
- The concerns related to the risks of developing peritonitis (fear of not doing the procedure correctly) in 5 patients.
- The anxiety of not being able to fulfil the tasks requested by the treatment (I can’t; I lack air when I have to start dialysis) in 6 patients.

**Conclusion:** This qualitative study performed in PD patients during the first 3 months of dialysis identified the most frequent causes triggering the request of a psychological referral. These findings may be of help for the physicians in order to identify which aspects need to be better discuss during the pre-dialysis counselling and stresses the importance of the availability of a psychological support in a PD unit.

**IS PERITONEAL DIALYSIS RELATED PERITONITIS A MAJOR RISK FACTOR FOR CARDIOVASCULAR EVENTS?**

Catarina Almeida, Maria Victoria Vaz Da Rocha Paes de Faria, Joana Pereira Dias, Daniela Lopes, Rute Carmo, João Carlos Fernandes, Maria Clara Almeida and Ana Marta Gomes

Centro Hospitalar Vila Nova de Gaia / Espinho, Nephrology, Portugal

**Background and Aims:** Cardiovascular (CV) disease remains the leading cause of death in peritoneal dialysis (PD) patients and traditional CV risk factors are unable to fully account for this high incidence. The aim of our study was to establish the incidence of CV events such as acute myocardial infarction (AMI) in the PD population and assess possible risk factors for its occurrence.

**Method:** We retrospectively studied patients on PD in our unit with a minimum 3-years dialysis vintage, between January 1st 2015 and April 30th 2022. Patients with previous CV disease were excluded. Demographic and clinical data were collected, such as traditional CV risk factors, AMI, peripheral artery disease, cerebrovascular events, as well as dialysis efficiency, hydration status obtained by Body Composition Monitor (Fresenius Medical Care) and PD-related infections before AMI or end of follow-up. Univariate analysis was performed and logistic regression was applied to access predictors of AMI.

**Results:** Of the 43 patients recruited, 53.5% were male, with a mean age of 56.4 ± 11.8 years. About 98% of patients were hypertensive, 21% were diabetic, 19% were obese, and 54% had dyslipidemia. Five (11.6%) patients had a CV event while on PD, 4 suffered AMI and 1 patient had an ischemic stroke. Patients’ characteristics are presented in Table 1. In the follow-up, peripheral arterial disease (p = 0.037), hyperphosphatemia (p = 0.035) and the cumulative number of peritonitis (p = 0.018) were associated with the occurrence of AMI. In our population we found a higher frequency of peritonitis in the year prior to the AMI (p = 0.024). In logistic regression, the cumulative number of peritonitis was a predictor of AMI (OR 4.918, CI 95%:1.093-22.132). In the mean follow-up time of 4.7 ± 1.4 years, the overall mortality was 21.7%, with CV disease accounting for 60% of the observed deaths. AMI and peritonitis were associated with higher mortality in PD patients (p = 0.016 and p = 0.009, respectively).

**Conclusion:** PD-related peritonitis was a predictor of AMI in these population. The risk is higher in the year following a peritonitis episode. This may be due to a chronic inflammatory state that persists after successful treatment of peritonitis which may predispose to enhanced CV risk. Similar to previous studies, we found that cumulative episodes of peritonitis were associated with increased mortality in PD population.
Table 1: Comparison between PD patients with and without AMI.

VALIDATION OF AN M-HEALTH TECHNOLOGY TO SUPPORT PATIENTS UNDERGOING PERITONEAL DIALYSIS
Analayde Lima de Azevedo1, Juliana Gomes Ramalho de Oliveira2, Rodrigo Tavares Dantas2, Rayndrick Kelryn Assis Lima3, Geraldo Bezerra Da Silva Junior2 and Karla Maria Carneiro Rolim1

1University of Fortaleza, Professional Master’s Degree in Technology and Innovation in Nursing, Fortaleza, Brazil, 2University of Fortaleza, Public Health Graduate Program, Fortaleza, Brazil and 3University of Fortaleza, School of Medicine, Fortaleza, Brazil

Background and Aims: A global increase in the prevalence of chronic kidney disease (CKD) and, consequently, in the number of individuals submitted to renal replacement therapy (RRT) has been observed. In Brazil, there was an increase from 46,557 to 144,779 (>310%) in the number of people on dialysis between the years 2001 and 2020, respectively. Although peritoneal dialysis (PD) is a safe, low-cost and less aggressive dialysis method when compared to hemodialysis (HD) and can be performed at the home, HD remains the most common RRT type in Brazil (92.2%). This study aimed to validate a PD section incorporated into an existing m-Health application (app) called ‘Renal Health®’.

Method: This is a methodological study, with a quantitative and applied approach. For internal validation of the app usability, ten specialists/researchers in the study topic from the Nursing Nephrology participated in the study, hereafter referred to as ‘judges’, who carried out the validation process of the content to be inserted into the Renal Health® app. The validation instrument was sent to them electronically, organized according to a Likert scale following a four-degree gradation. Based on the specialists’ answers, the means of agreement were calculated, which ranged from –1 for a negative evaluation; 0 (zero) for a neither positive nor negative evaluation; and, +1 when the evaluation was positive. Data evaluation was done using descriptive statistics and the calculation of the content validity index (CVI). Each item of the validation instrument was analyzed in relation to these obtained averages, which, if they were less than 80%, would indicate the need for modifications. An evaluation instrument was created with 22 items arranged in three domains: objectives (4), structure and presentation (15), and relevance (3), aiming to reflect the app functionality, usability and appearance.

Results: Regarding the objectives related to the PD section, none of items received an “irrelevant” assessment and its CVI ranged from 0.90 to 1.0, with an overall CVI of 0.95. The sub-items with the highest scores were related to the text being compatible with the target audience and the PD section of the app having adequate information/content to guide the patients. Among the 15 sub-items related to the structure and presentation of the PD section, six showed 90% agreement among the judges and were distributed as follows: they indicated that the information directed to the object of interest was sufficient and adequate; stated that the colors applied to the text were relevant and facilitated its use; that the subtitles applied were adequate and helped the user to understand the image; confirmed that the amount of illustration was adequate for the content of the material; that the illustrations were clear and easy to understand and that they were relevant to the content of the material and elucidated the content. The other sub-items had a maximum CVI (1.0) and the

Figure 1: Initial prototype of the PD section of the Renal Health® application.
overall CVI for this domain was 0.95. Finally, regarding the relevance of the PD section, all sub-items showed 100% agreement among the participants, so that the overall CVI was 1.0. Regarding the qualitative analysis of the instrument, there was no disagreement between the judges and/or suggestions for changes in the PD section.

Conclusion: The present study allowed the validation of the PD section in the Renal Health® app, which showed good reliability and could promote the use of m-Health technology to support users undergoing this type of dialysis.

PERITONEAL INFLAMMATION INDUCES SYSTEMIC ERYPTOSIS IN PERITONEAL DIALYSIS-ASSOCIATED PERITONITIS
Grazia Maria Virzi, Sabrina Milan Manani, Davide Marturano, Maria Mattiotti, Ilaria Tantillo, Claudio Ronco and Monica Zanella
1San Bortolo Hospital and IRRIV, Vicenza, Italy and 2Department of Medicine, Nephrology, Dialysis and Transplantation Unit, University of Padua, Padova, Italy

Background and Aims: Eryptosis is stress-induced RBC (Red Blood Cell) death mechanism. Our preliminary data show that there is a significant increased of eryptosis during peritoneal dialysis-associated peritonitis. Furthermore, there is an elevation of local and systemic inflammatory mediators. The aim of this study was to evaluate the relationship between systemic eryptosis levels in peritonitis and specific peritonitis biomarkers in peritonitis effluent (PDE), such as Peritoneal White Blood cell count (pWBC), peritoneal NGAL (pNGAL) and peritoneal cytokines levels.

Method: We enrolled 22 PD patients with peritonitis and 17 healthy subjects. PD-related peritonitis was defined according to the Guidelines of the International Society of Peritoneal Dialysis. At the time of diagnosis, blood samples were collected for eryptosis and peritoneal effluent were taken to evaluate pWBC, pNGAL and cytokines. All eryptotic measurements were made in freshly isolated RBCs. PS avidly binds AnnexinV, which is thus employed to identify eryptotic cells. Thus, PS exposure at RBC surface was estimated from FITC-AnnexinV binding using flow cytometric analyses.

Results: 13/22 patients were treated with continuous ambulatory PD (CAPD) and 9 with automated PD (APD). The median length of PD treatment was 28.1 months and the range was: minimum: 3 – maximum: 124.9 months. The percentage of AnnexinV-binding RBCs was significantly higher in PD patients with peritonitis than in CTR (PD patients with peritonitis: 7.7; IQR 4.3-14.2, versus CTR: 0.7; IQR 0.7-1.3; p<0.001) (Figure 1). WBC, NGAL and cytokines levels in PDE are reported in Table 2. We observed important correlation between eryptosis levels and peritoneal biomarkers (Figure 2).

Conclusion: In conclusion, we investigated a potential connection between systemic eryptosis and peritoneal biomarkers involved in peritonitis. The presented results revealed that upregulated inflammatory markers could be the cause of high levels of systemic eryptosis during PD-related peritonitis.

THE ASSOCIATION BETWEEN SERUM CHEMERIN AND PERITONEAL MEMBRANE TRANSPORT FUNCTION IN INCIDENT PERITONEAL DIALYSIS PATIENTS: A PROSPECTIVE COHORT STUDY
Zhiyuan Zhang1, Xiaofang Wu1, Xiaoxiao Xia1 and Zi Li1

1Department of Nephrology, Institute of Nephrology, West China Hospital of Sichuan University, P.R. China and 2Department of Nephrology, The Third Affiliated Hospital of Chongming Medical University, P.R. China

Background and Aims: Some biomarkers in drained dialysate or peritoneal membrane have been found related to the dialysate/plasma ratio of creatinine at 4 h (D/P Cr) in patients undergoing peritoneal dialysis (PD). But so far, there is no report on serum markers. Some biomarkers are associated with cardiovascular diseases (CVDs). Chemerin is a multifunctional chemotactic adipokine which plays roles in inflammation, adipogenesis and metabolism. In this study, we intended to investigate the role of chemerin in the peritoneal membrane transport function and CVDs in incident PD patients.

Method: This prospective cohort study was conducted in our PD center. The patients underwent initial standardized peritoneal equilibration test (PET) after PD for 4–6 weeks. Level of serum chemerin was determined via enzyme-linked immunosorbsent assay (ELISA). The patients’ CVDs were recorded during the follow-up period.

Results: 151 eligible patients with a mean age of 46.59±13.52 years were enrolled. And the median duration of PD was 25.0 months. The median concentration of serum chemerin was 29.09 ng/mL. Baseline D/P Cr was found to be positively correlated with serum chemerin (r = 0.244, p = 0.003). The multivariate analyses revealed that serum chemerin (p = 0.002), age (p = 0.044), albumin (p = 0.000), and high-density lipoprotein (HDL) (p = 0.022) were independent factors of D/P Cr. The serum chemerin level was significantly higher in diabetes mellitus (DM) patients than that of patients without DM (36.45 vs 27.37 ng/mL, p = 0.000). And there was a significant statistical difference in CVDs between the high chemerin group (>29.09 ng/mL) and low chemerin group (<29.09 ng/mL) (42% vs 21%, p = 0.009).

Conclusion: Serum chemerin has a positive correlation with baseline D/P Cr in incident PD patients. It may be a biomarker that can predict the baseline transport function of peritoneal membrane. And serum chemerin may be a risk factor of CVDs for incident PD patients. Multicenter studies with a larger sample size are warranted in the future.

PERITONEAL DIALYSIS INFECTIONS IN MALTA: AN OVERVIEW OF THIRTEEN YEARS
Abigail Attard1, Edward Grech1, Angela Borg Cauchi1, Jesmar Buttigieg, Emanuel Farrugia1 and Michael A. Borg2

1Mater Dei Hospital, Malta, Nephrology, Malta and 2Mater Dei Hospital, Malta Infection Control & Sterile Services, Malta

Background and Aims: Peritoneal dialysis (PD)-related infections are still associated with an increased risk of morbidity and mortality. We describe an overview of PD peritonitis and catheter-related infection (CRI) rates in Malta over a period of thirteen years.

Method: All patients undergoing PD in Malta from 2008 to 2020 were included. Data from 2008 to 2012 was retrospective (shown as mean), whilst data from 2013 to 2020 was prospective. ISPD guidelines and definitions were followed.

Results: Study population sizes from 2008 to 2020 were as follows: 137 (2008-2012), 91, 80, 126, 117, 102, 103, 101, and 101 respectively. PD peritonitis rates from 2008 to 2020 were 0.38, 0.31, 0.35, 0.46, 0.43, 0.57, 0.54, 0.43, 0.39, 0.40, 0.46, 0.37, and 0.29 episodes/patient/year respectively. Gram-positive peritonitis episodes predominated, the majority of which were Staphylococcal infections. Methicillin-resistant Staphylococcus aureus (MRSA) rates have overall decreased from 0.03 episodes/patient in 2008–2012 to 0.01 episodes/patient in 2020, to no cases in 2016, 2017 and 2019. Coagulase-negative Staphylococcal (CNS) rates also decreased from 0.26 episodes/patient in 2013 to 0.03 in 2017, 0.11 in 2018, 0.04 in 2019, and 0.08 in 2020. With regards to Gram-negative peritonitis, Pseudomonas rates declined from 0.06 episodes/patient in 2008–2012 to 0.03 in 2018. No cases were recorded in 2016, 2019 and 2020. The rate of Escherichia coli-associated peritonitis was 0.03 episodes/patient/year in 2020, and no cases were found in 2016, 2017, 2018, and 2019. Fungal peritonitis rates varied from 0.03 in 2008–2012 to 0.01 episodes/patient/year in 2013, 2018, 2019 and 2020 with no cases being recorded in 2016 and 2017. CRI rates were as follows: 0.39 (2008-2012), 0.35, 0.91, 0.37, 0.38, 0.25, 0.50, 0.29, and 0.22 episodes/patient/year respectively. The incidence of Gram-negative infections from 2013 to 2020 was 49, 51, 52, 65, 58, 66, 48, 41% respectively, with an average rate of 54%. Gram-positive CRIs were mostly Staphylococcal, peaking in 2014 at 0.38 episodes/patient, down to 0.14 in 2019, and 0.10 in 2020. MRSA rates decreased from 0.15 episodes/patient/year to 0.04 in 2018, no cases in 2019, and 0.04 in 2020. CRI Pseudomonas rates have overall improved from 0.12 (2008-2012), to 0.06, 0.09, 0.09, 0.14, 0.03, 0.17, 0.06, 0.04 episodes/patient/year from 2013 to 2020.

Conclusion: The Maltese PD cohort has been achieving ISPD target requirements. Both PD peritonitis and catheter-related infection rates declined over the last thirteen years. There was no MRSA peritonitis in 2016, 2017 and 2019, no Pseudomonas peritonitis in 2016, 2019 and 2020, no E. coli in 2016,2017, 2018 and 2019 and no fungal PD peritonitis in 2016 and 2017. Overall CRIs were predominantly Gram-negative, but not in 2019 and 2020.

PERITONEAL DIALYSIS AFTER FAILED KIDNEY TRANSPLANT: A SUITABLE OPTION
Diogo Francisco, Andreia Carnevale, Gonçalo Ávila, Ana Rita Calça, Patricia Matias and Patricia Branco
Hospital de Santa Cruz, Centro Hospitalar Lisboa Ocidental, Nephrology Department, Carnaxide, Portugal

Background and Aims: Despite great advances in graft survival, kidney transplant (KT) recipients frequently return to dialysis. The aim of this study was to perform an analysis of peritoneal dialysis (PD) outcomes of patients with a failed KT.

Method: Single-center retrospective cohort study with end-stage renal disease (ESRD) patients who started PD from 1st January 2010 to 31st December 2017. Two groups were analyzed: patients who started PD with no previous renal replacement therapy (RRT) - PD first -, and patients who transitioned directly from a failed kidney transplant.

Results: Among 152 patients who started PD, 115 were PD first and 15 transitioned from KT. The population included 63.1% of male gender, with a mean age of 52.4 ± 15.5 years and had PD median vintage of 30 months (IQR 20,6). Patients who transitioned from KT were significantly younger (mean age 42.8 ± 14.3 vs 53.7 ± 15.3, p = 0.015) and had lower prevalence of diabetes mellitus (13.3% vs 40.0%, p = 0.044). In KT patients, glucocorticoids were continued until there was residual diuresis and non-glucocorticoid immunosuppression was maintained for a median of 180 days (± 176) after PD start. Nearly a third (30.0%) of patients had no hospitalizations and 35.5% had more than 2 hospital admissions. Annual hospitalization rate was higher in prior KT group (1.40 vs. 0.48, p = 0.002). Prior KT associated with higher annual peritonitis rate (0.70 vs. 0.20, p = 0.017). A higher number of MACE was also observed in prior KT group (33.3% vs. 7.9%, p = 0.004). Residual diuresis was significantly lower in the group with previous KT. Neither ultrafiltration failure (6.7% vs. 9.9%, p = 0.974), nor technique survival (death or hemodialysis transfer 53.3% vs. 54.8%, p = 0.917; logrank 0.354) were different between groups.

Conclusion: Although higher incidence of diabetes mellitus was observed in PD first group, no differences were identified in ultrafiltration failure rates between groups. Despite significantly lower diuresis in prior KT group, both groups had adequate dialysis efficacy (mean Kt/V>1.7) and similar technique survival. Higher peritonitis rate and MACE incidence was observed in prior KT group, possibly associated with maintenance immunosuppression. Nevertheless, PD is a valid choice for RRT after a failed KT and should be offered to these patients.

EMERGENCY DEPARTMENT VISITS IN PERITONEAL DIALYSIS PATIENTS: A SINGLE CENTER STUDY DURING AN 8-YEAR PERIOD
Lamiyya Neymatova¹, Dilek Barutcu Atas², Murat Tugcu³, Arzu Veloğlu³, İzzet Hakki Arikane and Ebru Asıcıoğlu²

1Marmara University School of Medicine, Internal Medicine, Turkey and 2Marmara University School of Medicine, Nephrology, Istanbul, Turkey

Background and Aims: Peritoneal dialysis patients may present to the emergency department (ED) with infectious, mechanical and metabolic complications of dialysis, as well as non-dialysis-related problems. We planned to retrospectively analyse ED visits in PD patients.

Method: Study included 189 PD patients followed between December 2014 and July 2022. Patients younger than 18 years and with less than 1-month follow-up were excluded. Demographic characteristics, co-morbidities, med-

Results: There were 32 (16.9%) female and 157 (83.1%) male patients. Patients were divided into two groups as those who applied to the ED (n = 109) or not (n = 80). Median age (47 (19-80) vs 52.5 (26-77) years, p = 0.389) and dialysis duration (41 (2-148) vs 20.5 (1-217) months, p = 0.390) were similar in both groups. Most common comorbidities were anaemia (103 (94.5%) vs 75 (93.8%), p = 1,000), hypertension (90 (82.6%) vs 64 (80%), p = 0.707) and diabetes mellitus (23 (21.9%) vs 17 (21.3%), p = 1,000). While mortality (39 (35.8%) vs. 16 (20%), p = 0.013) was significantly higher in patients presenting to ED, transfer to hemodialysis (29 (26.6%) vs 33 (41.3%), p = 0.008) and transplant (4 (3.7%) vs 12 (15%), p = 0.042) were lower. There were 248 ED admissions for 109 patients during follow-up. Ninety-two (37.1%) episodes required hospitalization, whereas 156 (62.9%) episodes were treated as outpatients. Mean hospital stay was 10.5 (1-103) days. Most common reasons for admission were abdominal pain, cloudy diuresis, nausea and/or vomiting in 111 episodes (44.8%), cardiovascular symptoms in 31 episodes (12.5%) and hypervolemia in 29 episodes (11.7%). Most common diagnoses were peritonitis in 61 (24.6%), hypervolemia in 32 (12.6%), and upper respiratory tract infection in 21 (8.5%) episodes. When patients were evaluated based on hospitalization status, mean patient age was higher in hospitalized patients (55 (17-84) vs 49 (15-87) years, p = 0.029), whereas residual renal function (RRF) was lower (150 (0-2500) vs 300 (0-9500) mL/day, p = 0.048). Laboratory data is shown in Table 1. In multivariate analysis, factors predicting hospitalization were CRP [0.991 (0.984-0.997), p = 0.003] and magnesium [5.315 (1.423-19.853), p = 0.013]. Patients presenting to ED were also evaluated based on mortality during follow-up and 39 (35.8%) out of 109 patients died. There was no difference in terms of patient age (p = 0.525), gender (p = 0.792), dialysis time (p = 0.536) or RRF (p = 0.377). However, number of ED admissions was significantly higher in patients who died (2.81±1.63 vs 1.99±1.26, p = 0.004) and the only factor predicting patient death was the number of ED admissions [1.603 (1.058-2.430) p = 0.026].

Conclusion: The most common symptoms associated with ED admissions were gastrointestinal and the most common diagnosis was peritonitis. In patients presenting to the ED, more than a third required hospitalization. Factors predicting hospitalization were high CRP and low magnesium levels. The number of admissions to the ED was the only factor that predicted death during follow-up.

THE UNEXPECTED BALANCE OF PROINFLAMMATORY CELLS IN PERITONEAL DIALYSIS PATIENTS
João Grilo1, Catarina Santos1, Andreia Monteiro2, Raquel Chorão1, Joana Coutinho1, Lígia Ribeiro1, Rui Filipe1 and Ernesto Rocha1
1Hospital Amato Lusitano, Nephrology, Castelo Branco, Portugal and 2Centro Hospitalar Universitário Covadiga Beira (CHUCB), Clinical Pathology, Covilhã, Portugal

Background and Aims: Chronic kidney disease (CKD) is a complex and heterogeneous disease and is increasingly becoming a global public health concern. It is characterized by a persistent inflammation state which appear to be caused by cytokines, growth factors and hormones. Peritoneal dialysis (PD) accounts for 9% of all kidney replacement therapy (KRT) and over time, some changes are expected to occur in the peritoneal membrane mainly due to exposure to PD solutions, infectious processes and non-infectious complications. This inflammatory process is poorly understood and needs further clarification, but Th17 cells and Th1 cells seem to be involved. Therefore, we aimed to quantify the frequency of peripheral immune cells and the concentration of IL-17A in peripheral blood (PB) and peritoneal effluent (PE) and compare to a healthy control group.

Method: In a cross-sectional study of 26 PD patients and 10 healthy, age and sex-matched controls we evaluated PB and PE frequencies of T lymphocytes, T CD4, T CD8 and Th1 cells by flow cytometry as well as IL-17 concentrations using enzyme-linked immunosorbent assay. Comparisons were performed between PD patients and controls and between the different groups of PD patients according to PD modality, number of exchanges, dialsate toxicity, extraneal use, infection and daily total volumes, type of peritoneal transport and volume indexes. Statistical analyses were performed using the SPSS statistics version 26.

Results: Table 1 summarizes the main characteristics of PD patients and controls. Overall, in comparison with the control group, the frequency of Th1 cells in PB of PD patients was significantly lower (P = 0.001). On the other hand, frequency of Th1 cells substantially expanded in the PE, as compared to the PB (P = 0.001). PD patients also presented lower Th17 cells frequencies (P = 0.061) and those prescribed Extraneal had the lowest frequencies of Th17 (P = 0.030). IL-17A concentration was significantly higher in PE vs PB of PD patients (P = 0.012). Finally, the frequency of total lymphocytes in high PD transporters was significantly higher in comparison with high-average transporters (P = 0.021).

Conclusion: In our cohort, PE presented high concentrations of proinflammatory cells and cytokines. Th1 cells rather than Th17 cells were increased, pointing to a predominant cytolytic activity but IL-17 was also increased. Treatment with Extraneal associated with a lower frequency of these cells, somehow counterbalancing the inflammatory milieu associated with high glucose concentrations.

ICODEXTRIN EFFICIENCY IN FLUID AND SODIUM REMOVAL REMAINS STABLE DURING LONG PERITONEAL DWELLS

Joanna Stachowska-Pietka1, Jacek Wanieowski1, Anna Olszowska2, Elvia Garcia-Lopez3, Zofia Wankowicz4 and Bengt Lindholm5

1Nalecz Institute of Biocybernetics and Biomedical Engineering, Polish Academy of Sciences, Warsaw, Poland. 2Military Institute of Medicine, Central Hospital of the Ministry of Public Defence, Warsaw, Poland and 3Karolinska Institute, Department of Clinical Science, Intervention and Technology, Division of Renal Medicine and Baxter Novum, Stockholm, Sweden

Background and Aims: Inadequate fluid and sodium removal has been shown to increase risk of overhydration and hypertension. In peritoneal dialysis, icodextrin-based solution provides sustained ultrafiltration, and therefore can be used for the long exchanges, especially in patients with fast solute transport rates in whom the effective ultrafiltration period is shortened. We investigated to which extent the efficiency of icodextrin in fluid and sodium removal is changing during 16-hour peritoneal dwells.

Method: Data on intraperitoneal volume, and concentrations of icodextrin and sodium in dialysate during 16 hours of peritoneal dwells with icodextrin-based solution were analysed in 11 clinically stable patients. Labeled serum albumin (RISA) was used as a volume marker and dialysate samples of 12 mL were collected at 8, 12, and 16 hours of peritoneal dwell. Residual volume was evaluated from marker dilution after 16 hours by rinsing peritoneal cavity with 2 L of fresh 1.36% glucose dialysis fluid. Ultrafiltration (UF) was calculated for each patient and each sampling time as the difference between drained and initially infused volume corrected for the sample volume. The total absorption of icodextrin-derived carbohydrates (AbsCHO) was calculated for each patient as the difference between initially infused and drained carbohydrates mass. The icodextrin ultrafiltration efficiency (UFE) was calculated for each sampling time as the ultrafiltration divided by the amount of icodextrin mass absorbed (AbsCHO). The efficiency of icodextrin in sodium removal (NaRE) was calculated for each sampling time as the sodium mass removed (difference between drained and initially infused sodium mass) divided by the corresponding icodextrin mass absorbed (AbsCHO). Correction for the residual volume and samples collections were applied for AbsCHO, UFE and NaRE calculations.

Results: After 16-hour dwell with icodextrin-based solution the ultrafiltration was positive in all except one patient, being on average (mean±SD) 669±369 mL. During the dwell, icodextrin was slowly absorbed from the peritoneal cavity, see Figure 1, left panel. At 16 hours, the mean cumulative CHO absorption (AbsCHO) reached 68.0±20.7 g (44±13% of initial CHO mass) while 56% of initial icodextrin mass infused still remained in dialysate, Figure 1, left panel. Icodextrin UF efficiency (UFE) calculated at 8, 12, and 16 hours remained stable (p = 0.6, ANOVA repeated measures) and was on average 9.9±5.8 mL/g, Figure 1, right panel. Moreover, icodextrin sodium removal efficiency (NaRE) also remained stable after 8 hours (p = 0.6, ANOVA repeated measures) and was on average 1.2±0.7 mmol/L/g, Figure 1, right panel. Conclusion: During 16 hours of peritoneal dialysis dwells with icodextrin-based solution, icodextrin was slowly absorbed with 56% of the osmotic agent remaining in the dialysate after 16 hours. The efficiency of icodextrin in terms

1University Hospital of Alexandroupolis, Nephrology, Alexandroupolis, Greece, 2University Hospital of Alexandroupolis, Nephrology, Alexandroupolis, Greece and 3University Hospital of Alexandroupolis, Surgery, Alexandroupolis, Greece

**Background and Aims:** Peritoneal Dialysis (P.D.) Adequacy includes a variety of targets such as the sufficient uremic toxins removal (Kt/V), patients’ euvolemia, acid-base and electrolyte balance etc.. Based on incremental PD prescription NIPD is often a reasonable modality choice when there is adequate Residual Renal Function (RRF). Eventually due to RRF decrease patients need to increase their PD adequacy by adding a solution during the day i.e Icodextrin (CCPD). The aim of this study was to evaluate the alteration of Cyclers’ ultrafiltration (UF) as well as Total Ultrafiltration (sum of Cycler ultrafiltration and the UF of the initial drainage) when transferring patients from NIPD to CCPD.

**Method:** This is a single center retrospective study of 16 patients (m = 9, f = 7). These patients were transferred from NIPD to CCPD due to inadequate PD adequacy. The patients’ mean age was 53.±19 years, their mean PD duration was 74.±25.7 months and their mean Peritoneal Solute Transfer Rate (PSTR-D/Pcr) was 0.69±0.12. We evaluated small solute clearance targets (Kt/V – ttotal, p:peritoneal, r:renal), RRF (eGFR, Vurine), Cycler ultrafiltration, the UF of the initial drainage and the sum of them (Total UF) on three consecutive days before the initiation of CCPD and three consecutive days after the initiation. The patients’ cycler treatment program remain constant and all of them received an initial day volume of 1000 ml with Icodextrin.

**Results:** We compared the alterations with Paired t-Test (normal distribution) We found a statistically significant improvement of the peritoneal fraction of Kt/V when applying CCPD (p = 0.01), on the other hand we found a statistically significant decrease from Cycler’s UF (p<0.05) as well as from Total UF (p<0.05) without any statistically significant increase in urine’s volume. Additionally, from the regression analysis there was statistically significant correlation between PSTR and ΔUF(UFNIPD–UFCCPD) showing that the faster the transporter the greater the ultrafiltration loss (p = 0.035, R = 0.58).

**Conclusion:** Transferring patients with adequacy problems from NIPD to CCPD improves small solute clearances but in some cases the risk for total ultrafiltration decrease is important and may lead to overhydration. It is necessary to contact perspective studies with hydration status evaluation ie Bioimpedance Spectroscopy.

**PERITONEAL DIALYSIS CATHETER LOCK: PREVENTING RELAPSES**

Jorge Marín, M. Jose Espigares Huete, Francisco Javier Ruiz Escolano, Elisa Pereira Pérez and Pilar Galindo

Hospital Universitario Virgen de las Nieves, Nefrología, Granada, Spain

**Background and Aims:** The incidence of peritonitis has markedly decreased in the last decades, nevertheless it remains one of the main causes of catheter removal and subsequent dialysis modality change. In the long-term severe peritonitis and relapses can lead to peritoneal membrane failure. Some bacteria can form biofilms in the peritoneal catheter lumen granting them resistance against antibiotics and thus being one of the causes for infection recurrences. To find a viable way to avoid or/and eradicate the bacterial biofilm in the peritoneal catheters given the importance of infections.

**Method:** We present the experience in our peritoneal dialysis unit in the coadjuvant treatment of peritoneal dialysis-associated peritonitis with peritoneal catheter locks in the past few years. We used two kinds of peritoneal catheter lock depending on the isolated germ and divided them in two groups. Group I for the gram-positive staphylococcus group and Group II for gram-negative germs, specifically pseudomon. We reported 12 cases from which 10 were the first episode of gram-positive staphylococcus (epidermidis and Aureus) peritonitis. For the treatment we locked the catheter with 350mg of daptomycin in 7ml of saline solution once a week without using the catheter for 12 hours. For the other 2 cases of pseudomona peritonitis we locked the catheter with taurodilone/urokinase during the exchange with icodextrin twice a week with a 12 hours dwell time until 9 locks were archived.

**Results:** We treated 12 patients (Table 1). Peritonitis was resolved without recurrences in 9 of 10 patients in group I. In one case were a Methicillin-resistant *Staphylococcus aureus* was involved there was no response to the treatment and the peritoneal catheter was removed. In Group II both patients resolved their peritoneal infection without recurrences.

**Conclusion:** In our study peritoneal catheter locking seems to avoid the biofilm and reduce the peritoneal infection recurrences.

WHEN SHOULD WE TRY TREATMENT FOR PERITONEAL SCLEROSIS?

Antigoni Martika1, Ioanna Lampropoulou1, Alexandra Ntemka2, Maria Tsamelasvili1, Kalliopi Pozoukidou1, Nikolaos Georgilas3 and Sofia Spai1

1General Hospital of Thessaloniki Agios Pavlos, Nephrology Unit, Thessaloniki, Greece and 2General Hospital of Thessaloniki G. Papageorgiou, Nephrology Unit, Thessaloniki, Greece

Background and Aims: Although it is very important to detect patients at increased risk of developing encapsulating peritonitis (EPS), there are not established predictors which would promote early diagnosis and treatment of EPS ensuring sustainability of peritoneal dialysis (PD). D-Dimers are considered a significant test in evaluation of peritoneal fibrinolysis activity and Ca 125 is used as an alternative marker for assessing the integrity of peritoneal membrane.[1] We examined prospectively a combination of these surrogate markers both in serum and effluent dialysate at the beginning of the study. In a cohort of 39 PD patients D-Dimers, Ca 125 and CRP along with a complete biochemical profile were tested both in serum and overnight effluent dialysate at the beginning of the study. In 9 patients, who presented with recurrent gastrointestinal symptoms, such as mild nausea, incidence of gastric discomfort or sense of bloating, CT imaging was performed for evaluation of potent EPS and thickening of the bowel wall was measured. The latter group of nine patients received tamoxifene for a period of approximately one year and both serum/effluent biomarkers and CT imaging were repeated at the end of this period.

Results: In Table 1 characteristics of patients are shown. At the beginning of the study CRP was the only biomarker that was different between the group with or without gastrointestinal symptoms (4±6mg/dl vs 0.8±1.1mg/dl, p = 0.04).

In patients, who received tamoxifene gastrointestinal symptoms improved. In these patients follow up with CT imaging demonstrated amelioration of bowel wall thickening compared to the beginning (3±1.2mm vs 2.1±0.4mm), which was not statistically significant. Moreover, Ca 125 in dialysate decreased (60.4±7.4 U/ml vs 27±2.7 U/ml, p = 0.04). No side effects were recorded. Five patients are still on PD, 3 patients died from unrelated causes and 1 was transferred to hemodialysis.

Conclusion: In this study neither D-Dimers, a test for the assessment of the peritoneal fibrinolysis activity, nor Ca 125 an alternative marker for assessing the integrity of peritoneal membrane helped us to distinguish patients at risk for EPS. In fact Ca 125 levels in the effluent were higher in the treated group just before initiation of treatment, although in some references it is proposed that it is minimized.[1,2] Clinical evaluation along with radiologic findings led us to the decision to treat patients with tamoxifene, which exerts a protective effect on the peritoneal membrane during both early and late stages of fibrotic disorders.[3] Despite the small number of patients in this study, bowel wall thickening showed a tendency to decrease and symptoms improved.

ANALYSIS OF IRON STATUS AND ITS INFLUENCING FACTORS IN INITIAL PERITONEAL DIALYSIS PATIENTS

Yuhao Peng and Zhong Hui

P.R. China

Background and Aims: Iron deficiency (ID) is an important cause of poor response to anemia treatment in dialysis patients. The initial status of iron metabolism in uremic patients when they enter peritoneal dialysis (PD) may affect the strategy of iron therapy. Therefore, we investigated and analyzed the initial iron indicator levels and ID in patients with end-stage renal disease undergoing continuous ambulatory peritoneal dialysis (CAPD), and discussed the possible influencing factors of ID and iron supplementation treatment strategies.

Method: The clinical data of patients who underwent PD for 1–3 months in West China Hospital, Sichuan University from January, 2011 to January, 2018 were collected. The clinical data including patients’ characteristics, medication (oral iron supplement and erythropoietin), iron indicators [ferritin, serum
iron, serum iron saturation (TSAT) and transferrin), hemoglobin (HB), serum albumin (Alb), blood lipids, C-reactive protein and IL-6, β2-microglobulin, electrolytes and other biochemical indicators, as well as PD-related parameters. ID or relative ID was defined as ferritin \(< 100 \text{ ng/mL}\) or TSAT \(< 20\%\) and absolute ID was defined as ferritin \(< 100 \text{ ng/mL}\) or TSAT \(< 20\%\) and absolute ID was defined as ferritin \(< 100 \text{ ng/mL}\) or TSAT \(< 20\%\). Person correlation and Spearman correlation were used for normal distribution and non-normal distribution measurement data, respectively. Kendall correlation was used for categorical variables. Multivariate linear regression was used to analyze the independent influencing factors of ferritin and transferrin saturation. Binary logistic regression was used to analyze the independent influencing factors of ID.

**Results:** A total of 633 adult patients with stable condition and complete iron metabolism data were enrolled. The mean age was 45.7±14.0 years (18-91 years). There were 397 males (61.1%) and 100 patients (15.8%) with diabetes. The mean HB level was 95.4±18.4g/L, the ferritin level was 277.9±278.1ng/mL, the TSAT 29.9±12.9%, and the transferrin level 1.89±0.4 g/L. Among them, 487 (76.9%) used oral iron therapy and 412 (65.1%) used erythropoietin. 156 (58.8%) had HB less than 100g/L, and 156 (44.2%) had ID. There were 32.2% patients with ferritin \(< 100 \text{ ng/mL}\) and 23.4% patients with TSAT \(< 20\%\). Among patients who used oral iron therapy, 16.2% had absolute ID and 39.6% relative ID. There was no correlation between ID and diabetes, cardiovascular disease, gender, age, Alb, high-sensitivity CRP, IL-6, most of electrolytes, β2 microglobulin, blood leukocyte count, dialysate serum creatinine ratio at 4 hours, D/P Cr (4h), and there was no correlation between ID and eGFR (\(r = 0.057\)). Serum magnesium level (\(r = -0.014, p < 0.001\)), body surface area (\(r = -0.112, p = 0.005\)) and triglyceride (\(r = -0.086, p = 0.03\)) were negatively correlated with ID. Transferrin level (\(r = 0.427, p < 0.001\)) and platelet count (\(r = 0.169, p < 0.001\)) were positively correlated with ID. Multiple linear regression analysis with serum magnesium, body surface area, triglyceride, platelet count and eGFR input showed that triglyceride (\(p = 0.001\)), body surface area (\(p = 0.05\)) and platelet count (\(p = 0.001\)) were independently correlated with ferritin. With transferrin saturation as the dependent variable, showed that only platelet count (\(p < 0.001\)) was independently associated with transferrin saturation. Binary logistic regression analysis model (dependent variable being presence of ID = 1) showed that body surface area (\(\beta = -1.055, p = 0.042\)), triglyceride (\(\beta = -0.295, p = 0.014\)), serum magnesium (\(\beta = 0.997, p = 0.040\)) and platelet count (\(\beta = -0.006, p = 0.014\), \(p < 0.001\)) were independently associated with ID.

**Conclusion:** ID is common in new PD patients in our hospital, with a ferritin level of less than 100 ng/mL in one-third of patients. Platelet counts were higher in ID patients. People with larger body surface area and higher triglyceride levels may have more iron stores. Our study showed new PD patients should pay attention to iron supplementation before and after PD catheterization. Intravenous iron supplementation should be considered in time for those who still have ID after oral iron supplementation. In addition, increased platelet count may predict the occurrence of ID anemia.

---

**#6918 PATIENT AND TECHNIQUE SURVIVAL ON PERITONEAL DIALYSIS: A RETROSPECTIVE STUDY**

Robert Scarmignan1, Gaetano Alfano2, Francesco Fontana2, Riccardo Magistroni2 and Gabriele Donati2

1Nefrologia, Modena, Italy and 2Modena, Italy

**Background and Aims:** Peritoneal dialysis (PD) is a well-established replacement therapy for patients with end-stage kidney disease (ESKD). Despite innovations in PD fluid composition, PD patients experience a high morbidity rate. In particular, patients on PD have a high likelihood to switch from PD to HD due to catheter malfunction, peritonitis and ultrafiltration failure. A considerable number of risk factors are associated with a high risk of death, almost comparable with patients receiving hemodialysis (HD). This study aimed to analyze the outcome of patients receiving PD.

**Method:** A single center-retrospective study was conducted at the University Hospital of Modena. We collected data from patients who started PD from 1996 to 2021. Data were extracted from electronic healthcare records. Subjects aged \(< 18\) years were excluded. Patients with pre-existing abdominal wall defects (i.e., hernia), low-back pain, obesity and active working life were treated by automated peritoneal dialysis (APD). Kt/V was performed at least 5 times per year. Low depeurative efficacy, ultrafiltration failure and severe abdominal pathology were causes of permanent transition from HD to PD. Baseline characteristics were described using mean and standard deviation (SD), or frequencies. The chi-square or Fisher's test, and student's t-test were used to compare categorical and continuous variables between groups. For survival analysis were used Kaplan-Meier and Cox regression methods. A P value of \(< 0.05\) was considered statistically significant. All statistical analyses were performed using SPSS® statistical software.

**Results:** During the observational period, 497 patients on PD were enrolled in the study. Mean age was 63.5 (±15.6) years. Most of them were male (61%). Overall, 62.1% of the patients had at least 3 comorbidities beyond ESKD. Patients were affected by hypertension (70.4%), dyslipidemia (56.9%), cardiovascular disease (53.5%), hyperuricemia (41.6%) and diabetes (15.7%). Only 20.3% of the patients were on therapy with renin-angiotensin system inhibitors. PD was commenced at eGFR of 7±2.1 ml/min and CAPD (65.1%) was the modality of choice at the start of PD. The mean follow-up was 2.9 (±2.4) years. At end of the follow-up, 204 (41%) switched from PD to HD, 137 (27%) died, 92 (18.5%) underwent kidney transplantation and 64 (12.9%) were alive. On average, the switch from PD to home HD occurred after 3.3±2.7 years. The likelihood of transition from PD to HD for this group of patients was 10.7%, 30.3% 52.3%, and 70.3% at 1-, 3-, 5-, and 7 years, respectively (Fig. 1A). Patients who switched to HD were more frequently affected by diabetes (\(p = 0.02\)), hyperuricemia (\(p < 0.001\)) and hypercholesterolemia (\(p = 0.001\)) than those who remained in DP. Overall, males anticipated of 1.1 years the transition to HD compared to the females (\(p = 0.006\)). All-cause mortality in DP patients was 100.3 per 1000 person-years. In patients aged \(< 75\) years, mortality accounted for 242.1 per 1000 person-years. Cumulative all-cause 1-, 3-, 5-, and 7-year mortality accounted for 8.8%, 26%, 40.4% and 55.1%.
In the present study all IPD group patients started PD with increment cessation of PD, whichever occurs first.

**Results:**

In the present study all IPD group patients started PD with increment cessation of PD, whichever occurs first.

**Background and Aims:** At its start, Peritoneal dialysis (PD) was implemented only in advanced renal disease with a myriad of symptoms and signs. However, many subsequent literatures have highlighted possible benefits of early rather than late start of PD. Nevertheless, when to start PD has been a matter of controversy. This debate has created a new era of starting dialysis early during the course of the disease, in a small dose that was termed ‘incremental’ dialysis. By this modality, the dose of PD, is low at the initiation of RRT, and could be progressively increased over time in parallel with the reduction of RKF. Although incremental dialysis is growing worldwide, there has been no substantial agreement on the benefits of this approach. Moreover, the few available observational studies have compared incremental versus full-dose PD, with controversial results. On the other hand, studies comparing incremental dialysis with the conservative management for non-symptomatic ESRD patients are mostly deficient in the published literature. The present work is a retrospective, case-control, longitudinal study, aimed to evaluate the adequacy of incremental peritoneal dialysis as a modality of renal replacement therapy in ESRD patients, and whether it adds superior benefits over the conservative and the standard peritoneal dialysis (STPD) management.

**Method:** Data were collected retrospectively from Complesso Integrato Columbus Policlinico Gemelli, nephrology and dialysis unit archives. The study comprising three groups: first included 23 patients who were managed with one exchange to achieve the target Kt/V, a mean CrCl of less than 3.6±0.8 ml/min/1.73 m² failed to reach adequacy even with two exchanges a day and needed to be transferred to full dose while those with a mean CrCl in between the above values could only achieve Kt/V above 1.7 with two exchanges per day.

**Conclusion:** Incremental peritoneal dialysis, a rapidly growing new modality, is superior to the conservative treatment in patients with end-stage renal disease that can be adequately applied to patients with a GFR of 4 ml/min or more without adding the burden of full dose dialysis.

**LAPAROSCOPIC VERSUS OPEN-SURGERY CATHETER PLACEMENT IN PERITONEAL DIALYSIS PATIENTS: A META-ANALYSIS OF OUTCOMES**

Guleed Abdijalil

Shaoxing People’s Hospital (Shaoxing Hospital Zhejiang University School of Medicine), Department of Nephrology, Shaoxing, Zhejiang, P.R. China

**Background and Aims:** The peritoneal dialysis catheter (PDC) can be placed either through the laparoscopic technique, percutaneous technique or surgical procedures. The utilization of these PDC placement procedures is based on successful placement and reduced risk of development of complications. The main objective of this study was to compare the complications associated with laparoscopic vs. open-surgery PDC placement procedure.

**Method:** Literature for this review was obtained from all databases; to studies published in the period between 1998 and 2019 using Stata Version 12.

**Results:** The results showed significant difference in catheter malfunction between the laparoscopic and open-surgery group (relative risk [RR] = 0.58; 95% CI: 0.42–0.8; P = 0.031). Furthermore, there was no significant statistical difference in dialysate leakage (RR = 0.77; 95% CI: 0.51–1.17, P = 0.116) peritonitis (RR = 0.8; 95% CI: 0.6–1.06, P = 0.349) and exit-site infection (RR = 0.84; 95% CI: 0.65–1.09, P = 0.834) between the laparoscopic and open-surgery PDC placement groups.

**Conclusion:** The laparoscopic PDC placement procedure was superior to open surgery in regards to catheter malfunction. Additionally, the choice of treatment procedure should put in consideration factors such as cost and comfortability of the patient.

CLINICAL SIGNIFICANCE OF NORMO-HYDRATION STATE IN PERITONEAL DIALYSIS PATIENTS

Amna Hashmi1, Reka P. Szabo2, Istvan Varga3, Laszlo Kardos4 and Jozsef Balla5

1 University of Debrecen, Faculty of medicine, Debrecen, Hungary,
2 University of Debrecen, Faculty of Medicine, Institute of Internal Medicine, Department of Nephrology, Debrecen, Hungary,
3 University of Debrecen, Faculty of Medicine, Institute of Cardiology, Debrecen, Hungary,
4 University of Debrecen, Faculty of Medicine, Institute of Infectology, Debrecen, Hungary and
5 University of Debrecen, Faculty of Medicine, Institute of Internal Medicine, Department of Nephrology, Debrecen, Hungary

Background and Aims: The assessment of fluid status in dialysis patients is of paramount importance. Managing persistent volume overload and instability during dialysis is a significant challenge, with concomitant symptomatic and asymptomatic intradialytic hypotension (IDH) that results in dialysis-induced myocardial ischemia (cardiac stunning) and long patient recovery times. Our aim was to estimate the status of hydration in our peritoneal dialysis population by body composition monitoring (BCM) device to modify our pharmaceutical and dialysis policy and to evaluate echocardiographic parameters of the RV functions in patients with end-stage renal disease (ESRD) undergoing PD.

Method: We used a Fresenius Body Composition Monitor (BCM), a whole-body bioimpedance spectroscopy (50 frequencies, 5–1,000 kHz), to assess the body composition of 15 patients on peritoneal dialysis in our centre. We measured body weight, 24 h diuresis and performed a BCM session. Analysed results of echocardiography focused on RV (tricuspid annular plane systolic excursion (TAPSE). As per statistics, comparisons between 2 groups done by students t test, Mann Whitney U test or Wilcoxon test. Correlation between data was done by Pearson or spearman correlation. And lastly categorical variables were assessed by fisher’s exact, and Chi squared test.

Results: Average age was 47 years old (SD 9.45 t-test p = 0.1154). Gender distribution was 54.3% of our patients were female. 8.6% of our patients were anuric, 91.4% had residual urine (more than 1 litre). TAPSE value were average 23.17 mm (±4.5). We measured over-hydration in 8 cases by BCM that followed dialysis policy modification. In 8 PD patients we measured more than 2 L volume overload (VO) with BCM followed by dialysis policy modification (fluid intake restriction, diuretic dose increasing, frequent solution exchange).

Conclusion: Our data raised the importance of regular echocardiography to identify it. More attention should be focused on improving BP and volume control and identifying treatment strategies that effectively lower further deterioration in PD patients. One way of doing this is monitoring with BCM. With this clinician can manage persistent overload in CAPD patients, to better modify the dialysis regime, restrict fluid intake and use diuretics, to all in all preserve LV and RV function, and to prevent deterioration of the peritoneal membrane, and most importantly improve their survival.

Figure 1: Septum thickness in Echocardiography and hydration status among CAPD patients: volume overload can lead to thicker septum.
Figure 2: Ejection fraction and hydration status among CAPD patients: hyperhydration often associated with weaker cardiac function.

Figure 3: TAPSE and hydration status: Hyperhydration correlate with lower ejection fraction and elevated calculated right ventricle pressure in CAPD patients, but this is not significantly blue dots represents patients' observations, red line demonstrates empirical trends.
**Figure 4:** Distribution of HF in PD and in HD/predialytic group. Ejection fraction categories were classified as HFrEF: left ventricular (LV) EF ≤ 40%; HF with mildly reduced EF (HFrEF): LVEF 41–49%; HFpEF: LVEF > 50% Values of Ejection fraction and TAPSE in CAPD patients due to volume overload.

## PERITONEAL DIALYSIS COMPLICATIONS IN PEDIATRICS: A TUNISIAN EXPERIENCE

Abir Abdellatif, Manel Jellouli, Abir Bousetta, Taha Sayari, and Tahar Gargah
Hospital Charles Nicolle, Tunis, Tunisia

**Background and Aims:** Peritoneal dialysis (PD) is the preferred chronic dialysis modality for children suffering from chronic end-stage renal failure (CKD). But, it presents different infectious and non-infectious complications, causes of important morbidity and mortality. In this study, we aimed to describe the different infectious and mechanical complications observed in children on PD and to investigate the risk factors for the occurrence of different infectious and mechanical complications.

**Method:** In this study, we retrospectively collected the records of 99 patients who were treated with PD within the last eleven years (2010-2020) in the department of pediatrics of the University Hospital Charles Nicolle of Tunis. Analysis examining possible risk factors were performed using parametric and non-parametric tests and multivariate logistic regression in multivariate analysis.

**Results:** Ninety-nine children were on PD. All our patients were on automated PD. The sex ratio was 1.02. The overall duration of the PD was 390 years with an average of 2.93 years: 1.92 years. The average age at the beginning of PD was 9.75 ± 4.67 years. Sixty-nine patients had infectious complications, of which 65 patients had 120 episodes of peritonitis (IP) with a rate of 0.41 episodes per patient-year, 10 patients had exit-site infection and 3 patients had a tunnel infection. Mechanical complications were noted in 63 patients with a catheter revision rate of 1 per 38 patient-months. We noted an hernia in six patients, hemoperitoneum in seven patients, pancreatitis in three patients and no cases of hydrothorax. Analysis of PD complications risk revealed the following factors: poor adherence to treatment (p = 0.018 and p = 0.011) and weight less than 15 Kg (p = 0.041, p = 0.02) for infectious complications and IP respectively, comorbidity (p = 0.005) for mechanical complications, comorbidity (p = 0.008) and history of PI (p = 0.46) for catheter revision.

**Conclusion:** Ongoing educational programs for doctors, nurses and caregivers are needed to limit infectious complications. A collaboration between the pediatric nephrologist and the pediatric surgeon is recommended to improve catheter insertion techniques and prevent mechanical complications.

De novo donor specific antibodies

Figure 1: Association between molecular mismatches calculated with PIRCHE, HLA EMMA, and HLA-A, -B, -Cw, -DRB1, -DQB1 antigen mismatches and de novo donor specific antibodies. Showing odds ratio and 95% confidence interval.

C, Denmark and 3 Aarhus University Hospital, Department of Clinical Immunology, Aarhus, Denmark

Background and Aims: Optimizing graft survival and diminishing anti-HLA sensitization are essential in paediatric kidney transplant recipients (KTRs) facing multiple retransplantations. Improved pretransplant risk stratification and donor selection using in silico molecular HLA matching could enhance personalized immunosuppression and improve outcomes. HLA EMMA is a new in silico method to predict B cell epitope mismatches, and its clinical applicability needs confirmation in paediatric transplantation. We investigated the association of HLA B cell epitope (HLA EMMA) and predicted HLA T cell epitope (PIRCHIE) mismatches with de novo donor specific antibodies (dnDSA), anti-HLA antibodies, rejection, and graft survival.

Method: We retrospectively analysed 49 consecutive paediatric KTRs aged 1 to 16 transplanted from 2009-2020 at a single Danish centre. The centre has a long tradition of steroid-free kidney transplantations in immunologically uncomplicated recipients, and 80% of the KTRs did not receive steroids. Donors and recipients were all high-resolution HLA typed, and HLA EMMA (v 1.00) and PIRCHIE (v 3.3.60) predicted the molecular mismatches. KTRs were screened with mixed and single bead antigen kits after the transplantation. Logistic regression analyses were performed to explore the association of molecular mismatches and dnDSA, sensitization, graft loss, and rejection.

Results: The median age of the KTRs was 11 years (IQR 8), with a median follow-up time of 5 years (IQR 5). 11.36% developed dnDSA (60% class II, 40% class I and II) within a median of 3.91 years (IQR 2.28; range: 2.22-9.20); 57.45% had detectable anti-HLA antibodies during follow-up. Six KTRs lost their graft. None of the graft losses were related to alloimmunity, and 5-year death censored (one KTR died) graft survival was 88%. The cumulative incidence of rejection was 4% (95% CI: -1.5; 5.5) after one year and 10% (95% CI: 1.6; 18.7) after five years. The mean PIRCHIE score was 368.47 (95% CI: -1.6; 18.7) after five years. The mean HLA EMMA class I mismatch was 30.02 (95% CI: 1.6; 18.7) after five years. The mean PIRCHIE score was 368.47 (95% CI: 1.6; 18.7) after five years. The mean HLA EMMA class I mismatch was 30.02 (95% CI: 1.6; 18.7) after five years. The mean HLA EMMA class II mismatch was 30.02 (95% CI: 1.6; 18.7) after five years. We found no association between PIRCHIE or HLA EMMA with dnDSA, sensitization, graft loss, or rejection in the logistic regression models. We did see a trend towards an increased odds ratio in PIRCHIE predicting dnDSA (odds ratio: 1.31 (95% CI: 0.96; 1.80)) (Figure 1).

Conclusion: We did not find evidence to support the inclusion of the prediction of molecular mismatches in our clinical practice. The role of molecular mismatches in a clinical setting has yet to be established.
transplantation, higher levels of intra-renal MPO+ neutrophils were found upon cold storage using UW compared to cold storage using HTK.

Conclusion: The inflammatory process during chronic kidney rejection is T-cell driven and may involve the IL17C cascade. The early phase is dominated by neutrophils with enhanced intra-renal expression of CXCL1 and CXCL2. Furthermore, the polarization of the T-cell driven immune response may change depending on the time point after transplantation.

INFLAMMATORY INTERSTITIAL FIBROSIS AND TUBULAR ATROPHY ARE ASSOCIATED WITH HIGHER EXPRESSION OF INTRAGRAFT GRANZYME-B+ AND PHOSPHOSMAD-3+ PROTEIN
Brijesh Yadav, Narayan Prasad, Vinita Agrawal, Vikas Agarwal and Manoj Jain
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Nephrology and Renal Transplantation, Lucknow, India

Background and Aims: Inflammatory interstitial fibrosis and tubular atrophy (i-IF/TA) is a prominent histological lesion reported in late biopsy and poorly associated with graft survival. Cytotoxic T cell secrets Granzyme-B, which cleaves cytoskeleton protein, and activates pro-IL-1β, and TGF-β into their active form, leading to inflammation, fibrosis, and the apoptosis in target cell. The association of Granzyme-B+ cytotoxic T cell and phospho-SMAD-3 expression has been not explored in i-IF/TA in depth. Therefore, in this study, we aimed to determine the circulating and intragraft profiles of Granzyme-B+ cytotoxic T cell together with fibrosis pathway mediator p-SMAD-3 expression in renal transplant recipients (RTRs) patients with biopsy proven i-IF/TA.

Method: The circulating frequency of CD3+CD8+Granzyme-B+ cytotoxic T (CTLc) was measured by the flowcytometry; serum and PBMCs culture supernatants Granzyme-B and proinflammatory cytokines TGF-β, IL-1β level by the ELISA. Intragraft Granzyme-B mRNA transcript expression by the RT-PCR and Granzyme-B+, pSMAD-3+ Cell was analyzed by the immunohistochemistry techniques. Independent T-test for continuous variables and Pearson correlation was applied for the different variables.

Results: The circulating frequency of cytotoxic-T cell (CD3+CD8+Granzyme-B+) in SGF vs i-IF/TA was (27.96±4.86 vs 23.19±3.85%, p = 0.011), CD3+ T cell was (66.08±6.8 vs 65.18±9.35%; p = 0.68), CD3+CD8+ T cell was (37.29±4.11 vs 34.68±5.43%; p = 0.28). Serum Granzyme-B level was in SGF vs IF/TA was (100.82±22.41 vs 130.32±46.60, p = 0.038 pg/ml), serum TGF-β level was (367.50±31.50 vs 318.81±48.39, p = 0.005), IL-1β level was (49.14±17.03 vs 63.69±23.13, p = 0.076). Intragraft Granzyme-B mRNA transcript expression in SGF vs i-IF/TA was (1.01±0.048 vs 2.10±1.02-fold; p<0.001). Granzyme-B+ cell/mm² count was (0.40±0.69 vs 2.20±1.27; p = 0.001). The intragraft phosphorylated SMAD-3+ cell was (3.70±1.82 vs 6.73±3.21; p = 0.008). Fig. 1. The intragraft Granzyme-B+ cell count was positively correlated with pSMAD-3+ cell (r = 0.315, p = 0.047). The frequency of circulating CTLc was negatively correlated with urine proteinuria (r = -0.51, p<0.001), serum creatinine (r = -0.28, p = 0.037) and eGFR (r = -0.28, p = 0.037). While urine proteinuria was positively correlated with serum Granzyme-B level (r = 0.343, p = 0.001), intragraft Granzyme-B mRNA transcript expression (r = 0.38, p<0.001).

Conclusions: Higher intragraft Granzyme-B+ Cytotoxic T-cell and phosphoSMAD-3 positive cells are associated with i-IF/TA in RTRs.

#6062
EFFECT OF KIDNEY TRANSPLANTATION ON ARTERIOULAR MOLECULAR PATHWAYS IN CHILDREN WITH PRECEDING PERITONEAL DIALYSIS
Maria Bartosova1, Conghui Zhang1, Iva Marinovic2, Rebeca Herzo2, Bettina Schaefer1, Gema Ariceta3, Karel Vondrak4, Klaus Kratochwill5, Verena Peters1 and Claus Peter Schmitt1
1University Hospital Heidelberg, Heidelberg, Germany, 2Medical University of Vienna, Wien, Austria, 3Vall d’Hebron University Hospital, Barcelona, Spain and 4Motol University Hospital, Czech Republic

Background and Aims: Patients on peritoneal dialysis suffer from progressive peritoneal membrane transformation and accelerated vascular disease, underlying molecular machineries have recently been described. Molecular effects
of kidney transplantation (KTx) on vascular and peritoneal pathophysiology following PD are hardly understood.

Method: Fat surrounded omental arterioles (i.e. not directly exposed to PD fluids) from age-matched (median 6.5 years) children with chronic kidney disease (CKD5, n = 8), 5 children on PD [neutral pH, low glucose degradation product content, median PD duration 22 (5,50) months] and 6 children, who underwent successful KTx 4-5 weeks after a median 22 (12, 36) months of PD were analyzed by digital histomorphometry. Following microdissection from fat tissue, arterioles underwent transcriptomic and proteome analyses, followed by Gene Set Enrichment Analysis (GSEA), weighted gene co-expression network analysis (WGCNA), gene ontology (GO) and protein interaction analysis (string-db.org). Key pathways were validated in independent, matched cohorts by quantitative immunohistochemistry (n = 15/group) and in vitro.

Results: 5000 most variable arteriolar transcripts (cut off p-value < 0.05 and |r| ≥ 0.9) were grouped into 23 modules by WGCNA, of which 8 significantly differed between CKD5, PD and KTx. Seven were specifically related to KTx and one module to PD. Four out of seven KTx specific modules resulted in significant GO terms summarized as fatty acid biosynthesis, negative regulation of RNA metabolism, cell cycle arrest, and apoptosis. The PD specific module was associated with muscle cell proliferation, detoxification and complement activation (with thrombospondin as most interconnected gene). Multi-omics analysis of KTx vs. PD demonstrated concordant upregulation of lipid and fatty acid biosynthesis with the hub gene fatty acid synthase (FASN) and downregulation of positive cell cycle regulation. In independent, matched cohorts, arteriolar abundance of thrombospondin and terminal complex component were higher in children on PD, arterioles from children after KTx had levels comparable to arterioles from children with CKD5. Key drivers of fibrotic process, arteriolar TGF-β and pSMAD2/3, were also higher in PD arterioles compared to CKD5 and persistently high after KTx. Arteriolar cell cycle arrest marker p16 and apoptosis marker cleaved Casp3 were higher after KTx as compared to PD and CKD5. FASN was abundant in intima and media layers of all arterioles, and three-fold higher after KTx then in children with PD and CKD5, respectively. Neutral lipids (oil red staining) were present in all three groups, more abundant in the media than in the intima, and two-fold increased in the media of children after KTx compared to children on PD (p = 0.018) and with CKD5 (p = 0.002). In vitro, methylprednisolone and tacrolimus, but not mycophenolate mofetil increased FASN abundance and activity in human umbilical arterial endothelial and vascular smooth muscle cells compared to media controls.

Conclusion: We for the first time comprehensively describe molecular pathways activated after KTx in children following a standard immunosuppressive regime. After KTx, arteriolar fatty acid biosynthesis, apoptosis and cell cycle arrest markers are increased as compared to arterioles from children with PD and CKD5; profibrotic pathways induced by PD are persistently activated.

#3687 KIDNEY TRANSCRIPTOME VARIES BETWEEN DONOR TYPES, WITH A DIFFERENTIAL RESPONSE TO ISCHEMIC PRECONDITIONING

Tiago Pinto Cordho1, Pauline Erpicum1,2, Margaux Navez2, Chenyu Zhang1, Laurence Poma1, Olivier Detty3,4 and François Jourjet1,2

1GIGA Cardiovascular Sciences - Liège University, Laboratory of Translational Research in Nephrology, Liège, Belgium, 2CHU Liège, Nephrology, Liège, Belgium, 3CHU Liège, Abdominal surgery and Transplantation, Liège, Belgium and 4GIGA Cardiovascular Sciences - Liège University, CRÉDEC, Liège, Belgium

Background and Aims: The prevention/attenuation of graft ischemic injury is a challenge in kidney transplantation. We developed two rat models to investigate the impact of mesenchymal stromal cells (MSCs) in the ischemic preconditioning of kidneys from Donors after Circulatory Death (DCD) and Donors after Brain Death (DBD).

Method: Under general anesthesia, rats underwent iv injection of saline (S-groups) or 1.5 10⁶ MSCs (MSC-groups) followed by either DBD (6hr of brain death) or DCD (6hr of anesthesia and 20min warm ischemia) models, resulting in 4 groups (S-DBD, S-DCD, MSC-DBD, MSC-DCD). Kidneys were then pre-conditioned after IGLI flush. One kidney was directly fixed and the other one immersed for 14 hours in IGLI at 4°C. Serum samples were collected before treatment (baseline) and at the time of kidney collection. Urine samples were collected by bladder puncture at the time of kidney collection. Renal function was evaluated. Kidney histology was assessed by PAS staining and KIM1 immunostaining. Total RNA was extracted from S-DCD vs S-DBD kidneys for RNAseq.

Results: BUN was increased after 6h of anesthesia (DCD) or brain death (DBD) (p < 0.01). SGR increased in both S-DBD and MSC-DBD but was lower in MSC-treated rats (MSC-DBD 0.5±0.2mg/dL vs S-DBD 0.7±0.1mg/dL; p = 0.037). Urinary KIM1 was lower in MSC-treated DBD (S-DBD 10±4.5 vs MSC-DBD 7±1.7; p = 0.03). Acute Tubular Injury (ATI) and KIM1 expression were higher in S-DBD (ATI: S-DBD 65±24% of surface vs S-DCD 39±27% of surface (p = 0.03) and KIM1: S-DBD 0.39±0.24% of surface vs S-DCD 0.10±0.09% of surface (p = 0.0002)). In MSC groups, there was a significant extension in both extension and KIM expression. RNAseq showed that proinflammatory and proapoptotic pathways were upregulated in DBD, whereas transmembrane transport and metabolic pathways were downregulated, compared to DCD.

Conclusion: The RNA profiles of the kidneys are different upon donor types, which may impact the response to MSC-based ischemic preconditioning.
CD40-TRAF6 signaling inhibition blocks trained immunity and promotes allograft tolerance.

SUSTAINED IL-6 SECRETION CAN LEAD TO AN AMPLIFIED INFLAMMATORY RESPONSE, MEDIATED BY THE ACTIVATION OF STAT3 AND NFKB VIA THE IL-6 AMPLIFIER LOOP
Mantabya Singh¹, Narayan Prasad¹, Vikas Agarwal² and Mohit Rai²
¹SGPGIMS, Nephrology, Lucknow, India and ²SGPGIMS, Clinical Immunology and Rheumatology, Lucknow, India

Background and Aims: Organ transplants are the preferred treatment for end-stage organ failure. Potent and specific immunosuppressive agents have significantly decreased acute allograft rejection following renal transplantation. A significant barrier to long-term kidney allograft outcomes is chronic antibody-mediated rejection (CABMR). Chronic inflammation is a major cause of late graft loss that is mediated by soluble mediators released by immune and non-immune cells. IL-6 is a crucial cytokine that plays a central role in developing chronic inflammation. Non-immune cells, such as fibroblasts, have recently been identified as mediating chronic allograft rejection by activating the IL-6 amplifier loop (IL-6 + IL-17). Our Aim of the study:- to study the effect of IL-6 + IL-17 on secretion of IL-6 in the culture supernatant of fibroblasts derived from renal biopsy of chronic antibody mediated rejection (CABMR) patients; -to see the effect of anti-IL-6 (Tocilizumab) and anti-IL-17 on the secretion of IL-6 from the fibroblasts derived from kidney tissue of chronic antibody mediated rejection (CABMR) patients; and -to elucidate the pro-inflammatory pathway leading to increased IL-6 secretion by induction of Amplifier loop.

Method: Fibroblasts from grafted kidney from CABMR patients (n = 6) were cultured and stimulated with IL-6 (20ng/μl), IL-17(50ng/μl), IL-6 plus IL-17 for 24 hours. Levels of IL-6, MCP-1 and CCL20 were estimated in culture supernatants by ELISA as marker of IL-6 amplifier loop activation. mRNA expression of IL-6, MCP1, CCL20, and SOCS3 genes were measured in the stimulated fibroblasts. Stimulated Renal fibroblast cells from CABMR patients were lysed with Lysis buffer and subjected to SDS–PAGE and western blotting with anti-phospho-STAT3 and anti-phospho-NFkB p65. Additionally, IL-6, MCP1, and CCL20 levels were measured in Healthy control (n = 10), CABMR (n = 20), and non-CABMR (n = 30) patients.

Results: IL-6 and IL-17 synergistically induced more IL-6, CCL-20 & MCP-1 production from fibroblasts in culture supernatant. Gene expression analysis of IL-6, MCP1, and CCL20 was significantly higher with synergistic activation of IL-6 and IL-17 as compared to either IL-6 or IL-17 alone, while SOCS3 gene expression was downregulated. Our results also suggested that IL-6 Amplifier loop activation induces the NFkB and STAT3 signalling pathway activation in the non-immune cells like fibroblast derived from CABMR patients. Additionally, concentrations of IL-6, CCL-20 & MCP-1 in sera were significantly higher in CABMR patients compared to non-CABMR patients (p<0.001). There was a significant reduction in IL-6 concentration in culture supernatant with IL-6 and IL-17 inhibitor together and mRNA expression of IL-6, CCL20 and MCP-1 was significantly reduced while SOCS3 gene expression was upregulated.

Conclusion: In humans after kidney transplantation, IL-6 amplifier activation plays an active role in chronic rejection responses. Inhibition of IL-6 with Anti-IL-6 (Tocilizumab) and inhibition of IL-17 with Anti-IL-17 together reduces markers of tissue injury (IL-6, MCP1, CCL20) and rejection of allografts. so, IL-6 amplifier may be a therapeutic target for Chronic transplant rejection.

**BIOLOGICAL EFFECTS OF A SHORT PERIOD OF NORMOTHERMIC MACHINE PERFUSION IN MARGINAL KIDNEYS: RESULTS OF A PROTEOMICS ANALYSIS**

Flavia Neri¹, Maurizio Bruschi², Giovanni Candiano³, Simona Granata⁴, Lucrezia Furian¹ and Gianluigi Zaza¹

¹University of Padova, Kidney and Pancreas Transplantation Unit, Italy, ²Gaslini Hospital, Italy and ³University of Foggia, Department of Medical and Surgical Sciences, Italy

**Background and Aims:** Renal normothermic machine perfusion (NMP) is an organ preservation method based on the circulation of a warm (35–37°C) perfusion solution through the renal vasculature to deliver oxygen and nutrients. However, the biological effects of this technique on the marginal kidneys are uncertain. We consequently used mass spectrometry to define the proteomic profile of kidney tissue and urine from eight organs, considered unsuitable for transplantation, reconditioned for 120 min using a Kidney Assist device.

**Method:** Biopsies were taken during the pre-implantation histological evaluation (T-1), at the start of back table preparation (T0), and after 60 and 120 min of perfusion (T60, T120). Urine was collected at T0, T30, T60, and T120. Multiple algorithms, support vector machine (SVM) learning and partial least squares discriminant analysis (PLS-DA) were used to select the most discriminative proteins during NMP.

**Results:** Statistical analysis revealed the upregulation of 169 proteins and the downregulation of 196 in kidney tissue during NMP. Machine learning algorithms recognized the top 50 most discriminative proteins, five of which were concomitantly upregulated (LXN, ETFB, NUDT3, CYCS and UQCRBC1) and six downregulated (CFHR3, C1S, CFI, KNG1, SERPINC1, and F9) in the kidney and urine after NMP. Functional analysis showed that the most upregulated proteins were involved in the oxidative phosphorylation system and ATP synthesis, whereas the downregulated proteins were involved in the complement system and coagulation cascade. Results were, then, validated by classical and highly conservative biomolecular lab techniques.

**Conclusion:** Our proteomic analysis revealed that even brief periods of NMP induce substantial metabolic and biochemical changes in marginal organs, which supports the use of this promising technique in the clinic.

**NIERKEUZE.NL: A WEB-BASED APPLICATION TO SUPPORT THE SHARED DECISION PROCESS FOR KIDNEY REPLACEMENT THERAPY BASED ON OUTCOME DATA IN THE NETHERLANDS**

H Peters-Sengers¹,², Roelof Coster³, António W Gomes-Neto⁴, Henriette Scholten-Greben⁵, Hans Bart⁶, Marc Ten Dam⁷, Lara Heuveling⁶, Aline Hemke⁶, Han de Ruiter⁸ and Stefan P. Berger⁴

¹Amsterdam UMC, location University of Amsterdam, CEMM (Center for Experimental and Molecular Medicine), Amsterdam, Netherlands, ²Amsterdam UMC, location University of Amsterdam, Department of Clinical Epidemiology, Biostatistics and Bioinformatics, Amsterdam, Netherlands, ³Ordina, Groningen, Netherlands, ⁴University Medical Center Groningen, Department of Nephrology, Groningen, Netherlands, ⁵Dutch Kidney Patient Association (NVN), Bussum, Netherlands, ⁶Nefrovisie, Utrecht, Netherlands, ⁷Dutch Kidney Foundation (NTS), Leiden, Netherlands and ⁸Hanzehogeschool, Groningen, Netherlands

**Background and Aims:** Access to individualized, evidence-based prognostics is needed to facilitate decision making about the clinical implications of whether to opt for kidney transplantation or long-term dialysis. We aim to implement a data-driven support tool (Nierkeuze.nl) that incorporates basic patient characteristics and treatment options.

**Method:** Consecutive patients (N = 14,275) above 18 years of age with end-stage renal disease (ESRD) who were eligible candidates for their first kidney transplantation and started renal replacement therapy between 2000 and 2019 were included from the national registries RENINE and NOTR. SF-12 quality of life data was obtained from RENINE and a local transplant database. Several algorithms were developed to predict waiting time, short- and long-term patient survival, graft survival, and quality of life according to factors that are known at ESRD. Probabilities of 3- and 5-year mortality were calculated using two-stage distinct Cox regression: 1) waitlist-mortality according to median time on the waiting list, 2) mortality after transplantation in remaining follow-up. Product and complement rules defined the final probabilities. No mortality on the waiting list was assumed for living donor transplants. Missing data were imputed. Model performance was evaluated by internally validated C-statistics and calibration plots.

**Results:** We included 4,889 deceased donor transplants, of which 990 were within the Eurotransplant Senior allocation Program (ESP), and 6,251 living donor transplants. Discrimination varied for patient survival models (C-stats: 0.68 deceased-ETKAS-TX; 0.58 for deceased-ESP-TX; 0.74 for living-TX; 0.64 for waitlisted-candidates). Survival models achieved good calibration by visual inspection across the range of predicted probabilities. Figure 1 illustrates a clear 5-year survival benefit of transplantation (living and deceased donor groups) compared with wait-listed candidates for a 65-year-old male with glomerulonephritis. Other developed algorithms of the support tool will be presented with an overview of the first experiences in the kidney failure clinic.

**Conclusion:** Nierkeuze.nl depicts the influence of anticipated waiting time, patient characteristics, kidney allocation program, and donor type on survival outcome of the different treatment options. Incorporating this individualized quantitative outcome information may provide valuable support for an informed choice by patients and potential living donors.

**ACHIEVED BLOOD PRESSURE AND CARDIOVASCULAR OUTCOMES IN PATIENTS WITH ADVANCED STAGE CHRONIC KIDNEY DISEASE**

Ehab Al-Sodany, Karolina Szummer, Franz Peter Barany, Olof Heimbürger and Marie Evans

Karolinska Institute, Solna, Sweden

**Background and Aims:** In patients with severely decreased eGFR (stage 4-5 CKD), efficacy of treating patients to a lower blood pressure (BP) target is uncertain. The Systolic blood Pressure Intervention Trial (SPRINT) demonstrated lower rates of a composite cardiovascular (CVD) endpoint and death in the intensive treatment group with a target systolic blood pressure (SBP) of <120 mmHg. This study has influenced guidelines; the updated 2021 Kidney Disease Improving Global Outcomes (KDIGO) now suggest lowering the SBP to < 120 mmHg, if tolerated. In this study we set out to investigate the association between SBP and CVD in a large cohort of nephrology-referred patients with CKD stage 3-5.

**Method:** We included patients ≥18 years participating in the Swedish Renal Registry (SRR-CKD) who had a first registered eGFR <60 ml/min/1.73 m² 2006-2017 with at least one recorded BP measurement and two outpatient visits within one year. We excluded individuals with a recorded SBP <100 mmHg or prior kidney failure replacement treatment. After the initial one-year observation period, we followed patients until the primary or death event occurred or until the end of the study period.

**Figure 1: Unadjusted association between systolic blood pressure and risk of MACE.**
secondary outcome was attained, or until December 31, 2017. The achieved average systolic BP, measured during routine out-patient care using any standard electronic or manual blood pressure device, was categorized into a priori defined categories. To align with SPRINT, the primary endpoint was Major Cardiovascular Events (MACE) defined as the composite of first myocardial infarction (MI), non-MI acute coronary syndrome, stroke, heart failure, or death attributable to CVD. The secondary endpoints were the individual components of the primary composite endpoint, all-cause death, or a composite of the primary endpoint and death. Demographics, body mass index, underlying kidney disease, and laboratory values at the start of follow-up were obtained from the SRR-CqD. Information on comorbidity, including Charlson comorbidity index was gathered from a linkage with the National Patient Registry; medications were obtained from the National Prescribed drug register. The primary endpoint and secondary endpoints were assessed by cause-specific Cox proportional hazards regression, adjusting for age, sex, history of CVD, Charlson comorbidity, plasma albumin, phosphate, diuretics, RAASi, betablockers, eGFR, and diastolic blood pressure. Missing data were handled through multiple imputation.

Results: In total 15,668 patients with a median eGFR 23 ml/min/1.73 m², mean age 71 years and 33% women were followed over a period of 2.8 years (IQR 1.4–5.0). There were 6359 patients (41%) experiencing the primary outcome; 2601 (11%) with a coronary artery event, 1427 (9%) MI, 1345 (9%) cerebrovascular event, and 5,480 (35%) patients died. The unadjusted analysis showed a J-shaped relationship between SBP and the primary outcome, with the lowest risk of events in patients with SBP around 125 mmHg (Figure 1). In multivariable models, there was a higher risk of experiencing the primary outcome if the average SBP was >150 mmHg (HR 1.09; 95% CI 1.0–1.19), the highest risk being in those with SBP above 160 mmHg (HR 1.40 with 95% CI 1.28–1.53) as compared to those with SBP 130–140 mmHg (Figure 2). We observed 30% lower risk of MI when the SBP was 100–120 mmHg after adjustments (HR 0.70 (95% CI 0.56–0.88) as compared to 130–140, and higher risk of MI at SBP >160 mmHg (1.78; 1.49–2.12) with 11% higher risk of MI with every 10 mmHg increase in SBP (HR 1.11; 1.07–1.14). The other cardiovascular endpoints, including all-cause mortality showed a similar pattern as the primary composite endpoint.

Conclusion: In patients with advanced stage CKD, SBP <120 mmHg is associated with lower risk of MI, but with lower risk of other cardiovascular outcomes or all-cause mortality. A SBP >140 mmHg was associated with higher risk of most cardiovascular events including cardiovascular mortality and all-cause mortality.
immunosuppression therapy enables KT to patients with high immunological risk and avoid prolonged time on the waiting list.

INCIDENCE AND SEVERITY OF COVID-19 IN RELATION TO ANTI-RBD IgG ANTIBODY LEVEL AFTER COVID-19 VACCINATION IN KIDNEY TRANSPLANT RECIPIENTS
Lianne Messchendorp1, Jan-Stephan Saunders1, Alferso C. Abrahams2, Frederike Remelman3, Pin Bouwman3, Rene Dorpel van den3, Luuk Hilbrands6, Celine Immoh1, Marlies Reinders1, Theo Rispens4, Maurice Steenhuis1, Marc Ten Dam3, Priya Vart1, Alko De Vries10, Marc Hennmelder4 and Ronald Ganjevoort1
1University Medical Center Groningen, Groningen, Netherlands, 2UMC Utrecht, Utrecht, Netherlands, 3Amsterdam UMC, locate LANC, Amsterdam, Netherlands, 4UMC+, Maastricht, Netherlands, 5Maasstad Hospital, Rotterdam, Netherlands, 6Radboud University Medical Center, Nijmegen, Netherlands, 7Erasmus MC, Rotterdam, Netherlands, 8Sanquin Research, Netherlands, 9Canisius Wilhelmina Hospital, Nijmegen, Netherlands and 10Leiden University Medical Center (LUMC), Leiden, Netherland

Background and Aims: Kidney transplant recipients (KTRs) remain at increased risk for severe COVID-19 after vaccination, most likely due to an impaired immune response. However, the exact clinical impact of this impaired response remains unclear. Therefore we analysed the relationship between antibody levels after vaccination and the occurrence and severity of COVID-19 in a large cohort of KTRs.

Method: All KTRs, living in the Netherlands, who received COVID-19 vaccination were invited to participate in this observational cohort study. At approximately 28 days after the 2nd vaccination blood samples were obtained by a home-based finger-prick method and analysed for IgG antibodies against the receptor-binding domain of the SARS-CoV-2 spike protein (anti-RBD IgG). Participants were classified as either seronegative or seropositive using an anti-RBD IgG threshold of 50 BAU/mL. Participants who previously experienced COVID-19 were excluded. Primary endpoint was the incidence of COVID-19 from the moment the blood sample for anti-RBD IgG measurement was obtained until 6 months thereafter. Multivariable Cox and logistic regression analyses were performed to analyse which factors affected the occurrence and the severity (i.e. hospitalization and/or death) of COVID-19.

Results: In total 12,159 KTRs were approached of whom 3,828 agreed to participate. In 2,885 subjects successful antibody measurement was performed after the 2nd COVID-19 vaccination. Among those, 1,578 (54.7%) became seropositive, whereas 1,307 (45.3%) remained seronegative. During a follow-up of 6 months, seropositivity was associated with a lower risk for COVID-19 incidence, also after adjusting for age, sex, socio-economic status and adherence to COVID-19 restrictions (HR 0.48 (0.27-0.86), p = 0.01). COVID-19 was also significantly less severe in seropositive as compared to seronegative participants (OR 0.14 (0.03-0.67), p = 0.01). When studied on a continuous scale, we observed a log-linear relationship between antibody level and risk for COVID-19 incidence (HR 0.52 (0.31-0.89) per tenfold higher anti-RBD IgG antibody level, p = 0.02). A threshold above which optimal protection was offered could not be detected. A similar association was found for COVID-19 severity.

Conclusion: In conclusion, antibody level after COVID-19 vaccination is associated in a log-linear relationship with the occurrence and severity of COVID-19 in KTRs. Therefore higher antibody levels, and not only reaching seropositivity, should be the aim of COVID-19 vaccination in KTRs. Immunosuppressed patients who have no or low antibody levels after vaccination should be offered repeat vaccinations, whether or not via alternative vaccination strategies, or passive immunization.

INTERNATIONAL COMPARISON AND TIME TRENDS OF FIRST KIDNEY TRANSPLANT RECIPIENT CHARACTERISTICS ACROSS EUROPE: A STUDY FROM THE ERA REGISTRY
Rianne Boenink1, Anneke Kramer1, Vianda Stel1, Kitty J Jager1 and Alberto Ortiz2
1ERA Registry, Amsterdam, Netherlands and 2Fundación Jiménez Díaz, Madrid, Spain

Background and Aims: Large international differences exist in the kidney transplantation (KT) rate across Europe. Countries might transplant a different group of end-stage kidney disease (ESKD) patients, but up to now an overview of recipient characteristics in first kidney transplant recipients in the different European countries is lacking. Therefore, the aim of this study was to give an overview as well as time trends in age, sex and primary renal disease (PRD) distribution of first kidney transplant recipients in Europe.

Method: The European Renal Association (ERA) Registry database was used to obtain data on adult patients receiving their first KT between 2010 and 2019 from 12 European countries. The numbers and percentages of recipients in each age, sex and PRD group were calculated by country, donor type and year. The first KT rate was calculated by dividing the number of first KT’s by the adult general population counts and multiplied by one million.

Results: In total, 99,543 patients received a first KT between 2010 and 2019 for all countries combined. The percentage of recipients aged 65 years and older varied greatly between countries, with Bosnia and Herzegovina having the lowest percentage (1%), and the Netherlands, Spain and Norway having the highest percentages (>25%). Similar results were found for deceased donor first KT, but for living donor first KT Spain was no longer among the countries with the highest percentage of recipients aged 65 years and older. The percentage of female recipients ranged between 33% in Austria and 38% in the Netherlands for total first KT, between 33% in Austria and 38% in Denmark for deceased donor first KT and between 30% in Austria and 39% in the United Kingdom for living donor first KT. When comparing the distribution of PRDs, Bosnia and Herzegovina had a relative high percentage of recipients with glomerulonephritis (35%), while Finland had a high percentage of recipients with diabetes mellitus (29%) and the Netherlands and Norway a high percentage of recipients with hypertension / renal vascular diseases (17% and 22% respectively). This distribution was similar for deceased and living donor first KT recipients. Over time, the most prominent change regarding the recipient characteristics was observed for the age of the recipient, with an increasing proportion of recipients aged 65 years and older from 18% in 2010 to 28% in 2019 for all countries combined, and with a similar trend observed in most countries.

Conclusion: We observed large differences in the recipient characteristics at first KT between European countries and over time, especially for the recipient age and PRD. These new insights in the distribution of recipient characteristics in the first KT population could elucidate which ESKD patients receive a KT.

#5465
RACE-FREE eGFR EQUATION IN KIDNEY RECIPIENTS: A DEVELOPMENT AND VALIDATION STUDY
Paris Institute for Transplantation and Organ Regeneration, Université Paris Cité, INSERM, U-970, AP-HP, France

Background and Aims: To assess the performances of the current eGFR equations, including the race-free CKD-EPI-2021, in the kidney transplant population, and compare these performances to a race-free kidney-recipient-specific (KRS) GFR equation.

Method: We included adult kidney recipients transplanted between 01/01/2000 and 01/01/2017 in 16 academic cohorts in Europe, the USA and Australia comprising 14 transplant centres and three clinical trials. Measured GFRs (mGFR) were assessed using 51Cr-EDTA, 99mTc-DTPA, inulin, iothalamate or iohexol clearance, according to the local practice. A KRS GFR equation was developed using additive and multiplicative stepwise linear regressions and its performance was compared to those of the current GFR equations. The performances were assessed with the P30 and the correct classification of chronic kidney disease (CKD) stage metrics.

Results: The study included 15,489 patients, having 50,466 GFR values both measured and estimated by creatinine-based equations. Among the current GFR equations, race-free CKD-EPI-2021 equation showed the lowest performance compared with MDRD and CKD-EPI-2009 equations. We then built a race-free KRS GFR equation based on an additive model including creatinine, age, and sex. We showed that using race did not increase the performance of the equation. We found that the race-free KRS GFR equation showed significantly improved performance compared with the race-free CKD-EPI-2021 equation and performed well in the external validation cohorts (P30 ranging from 73.0% to 91.3%). Finally, we showed that the race-free KRS GFR equation performed well in a series of kidney transplant recipient subpopulations stratified by race, sex, age, body mass index, donor type, therapeutics, creatinine and GFR measurement methods and timing. Based on these results we developed an online application that estimates GFR
Based on recipient age, sex and creatinine: https://transplant-prediction-system.shinyapps.io/eGFR_equation_KTX/

Conclusion: Using multiple, international cohorts of kidney recipients, we developed and validated a new race-free KRS GFR equation that demonstrated high accuracy and outperformed the race-free CKD-EPI-2021 equation developed in individuals with native kidneys.

#4624

DO WOMEN HAVE LESS ACCESS TO THE KIDNEY TRANSPLANTATION WAITING LIST THAN MEN IN FRANCE?
Latame Komla Adoli1, Valérie Chattelet Pouliquen2, Eric Daugas3, Thierry Lobbedez4, Elsa Vabret5, Jean-Philippe Jais5, Florian Bayer6, Cécile Vigneau7, Cécile Couchoud5 and Sahar Bayat1

Background and Aims: Studies performed in several countries and in some French regions showed that women have less access to kidney transplantation waiting list (KTWL) than men. The aim of this study is to analyse women’s access to the kidney transplantation waiting list at the national level and in all French regions.

Method: This is a retrospective cohort study using the French National Renal Epidemiology registry (REIN). All incident patients initiated dialysis from 2017 to 2019 and aged between 18 and 85 were included. Patients were followed three years from the dialysis start. Our outcome of interest was the registration on the KTWL 1 and 3 years following dialysis initiation. We performed Cox proportional hazard models, adjusted on age, comorbidities and neighbourhood deprivation level using European Deprivation Index (EDI), at national level and in all French regions. The sex/age and sex/EDI interactions were studied.

Results: 29 395 patients started dialysis in 2017-2019. 35% were women. 40% of female and 34% of male patients lived in most deprived areas. Men were more comorbid than women at dialysis start. At the national level, women had less access to the KTWL compared to men one (adjHR: 0.91; IC95: [0.87 – 0.96]) and three years (adjHR: 0.87 [0.84 – 0.91]) after dialysis start. There was no significant sex/EDI interaction but a significant sex/age interaction. Therefore, the analyses were stratified by age (<60 and > 60 years old). Only women aged more than 60 had less access to the KTWL at one year (adjHR: 0.76 [0.71 – 0.82]) and three years (adjHR: 0.75 [0.71 – 0.81]). At regional level, the same trends were found in Nouvelle Aquitaine and Pays de Loire one-year after dialysis start and two more regions (Bourgogne-Franche-Comté and Île-de-France) 3 years after dialysis start.

Conclusion: This study shows that women have less access to KT WL one and three years after dialysis start at the national level and in some regions. This disparity is found to be present especially among patients aged beyond 60 years. A qualitative study is planned to better understand this sex based disparity.

#6327

ACCEPT OR DECLINE? A STATISTICAL APPROACH TO AID DECISION MAKING
Maria Ibrahim1, Jenny Mehew1 and Martin Utley2

1NHS Blood and Transplant, Filton, United Kingdom and 2University College London, United Kingdom

Background and Aims: The clinician-patient decision of whether to accept or decline an offered deceased donor kidney is one of the most complex in transplantation. Though many attempts have been made to risk stratify based on donor and recipient characteristics as well as other methods, reliance on clinical intuition remains high. We used a novel statistical modelling technique to better understand potential outcomes for patients following acceptance or decline of a deceased donor organ offer in the UK.

Method: We obtained UKTR data held by NHS Blood and Transplant (NHSBT) on adult patients listed for kidney transplantation in the UK, deceased donor kidney offers and post-transplant outcomes. Multivariable models to demonstrate 5-year transplant survival (a composite of graft and patient survival) for patients from the point of offering and post-transplant survival were developed using a Cox proportional hazard techniques. Waiting time to a “better” offer was modelled using a micro-simulation approach for patients and donors with different profiles, incorporating the points system from the current UK kidney offering scheme. Rates of patients arriving on the waiting list, leaving the list and being transplanted were obtained to facilitate this, as well as characteristics of waitlisted patients and organ donors. Simulations were then run to ascertain potential outcomes from the point of offer for an index patient for scenarios characterised by offers from donors with differing profiles.

Results: Figure 1 demonstrates the outcomes of an index patient if they accept an organ offer from a donor with the demonstrated characteristics compared with potential outcomes if the next offer is accepted. Figure 2 uses the same techniques but demonstrates outcomes if a kidney from a donor with ‘worse’ characteristics is offered.

Conclusion: This study demonstrates a novel method to help visualise potential outcomes for patients listed for deceased donor kidney transplantation. Though many attempts have been made to risk stratify based on donor and recipient characteristics as well as other methods, reliance on clinical intuition remains high. We used a novel statistical modelling technique to better understand potential outcomes for patients following acceptance or decline of a deceased donor organ offer in the UK.
KIDNEY TRANSPLANTATION IN PATIENTS WITH AA AMYLOIDOSIS: A FRENCH MULTI-CENTER MATCHED COHORT STUDY IN THE ERA OF BIOTHERAPIES

Background and Aims: Outcomes of kidney transplantation for patients with renal AA amyloidosis are uncertain, with reports of poor survival and high
Figure 1: Kaplan-Meier estimates of patient survival (A) and death-censored graft survival (B) in AA amyloidosis patients and in controls. Tables represent patients at risk in each group. Statistical difference was assessed with the Log-rank test.

Figure 2: allograft recurrence. However, recent advances in biotherapies, especially anti-IL-1 treatments, may have improved patients’ outcome in the transplantation setting.

Method: We conducted a retrospective multicenter matched cohort study in 26 French centers reporting all patients with AA amyloidosis who received a kidney transplant between 2008 and 2018, and compared them to matched control patients (ratio 1:2 controls) who received a kidney transplant for other causes.

Results: Eighty-six AA amyloidosis transplants and 157 control transplants were included. Median age was 49.4 years (interquartile range 39.7-61.1), and the main cause of amyloidosis was Familial Mediterranean Fever (37 cases, 43%). Sixteen (18.6%) patients received a biotherapy after transplantation. At 5 years, patient survival was 85.5% (95% confidence interval 77.8-94.0) and 86.2% (80.5-92.2) for cases and controls, respectively (p = 0.5). Death censored graft survival was 78.2% (78.2-93.5) and 91.7% (87.0-96.6), respectively (p = 0.05). Histologically proven AA amyloidosis recurrence was found in 5 patients (5.8%). 55.8% of amyloid patients had at least one infection requiring hospitalization and 27.9% an episode of acute graft rejection. In this group, multivariable analysis showed that CRP concentration at time of transplantation was associated with patient survival (HR 1.01, p = 0.01).

Conclusion: In this recent cohort, patient survival was comparable to controls and recurrence rates were lower than previously reported. Provided the underlying inflammatory disease is well controlled, patients with AA amyloidosis may be transplanted with similar patient and graft outcomes than that of matched controls.

#6440 C1Q-BINDING ANTI-HLA DONOR-SPECIFIC ANTIBODIES AND LONG-TERM KIDNEY GRAFT OUTCOMES
Michał Gnieśkiewicz1, Katarzyna Czerwińska1, Katarzyna Zielniok2 and Magdalena Durlik1

1Medical University of Warsaw, Department of Transplantation Medicine, Nephrology and Internal Diseases, Warsaw, Poland and 2Medical University of Warsaw, Department of Clinical Immunology, Warsaw, Poland

Background and Aims: Immunological response mediated by anti-HLA donor specific antibodies plays an important role in renal allograft injury in kidney transplant recipients. Several characteristics of donor-specific antibodies such as HLA class, specificity, mean fluorescence intensity, IgG
subclass and C1q-binding capacity can be assessed. The aim of this study was to determine the impact of circulating anti-HLA donor-specific and their characteristics, including C1q-binding capacity, on long-term kidney graft outcomes.

**Method:** One hundred eight patients from our transplant center, who underwent kidney allograft biopsy within three to twenty-four months after renal transplantation from brain-dead deceased donor between 2018 and 2020, were included in the study. At the time of biopsy patients' sera were collected and stored for analysis. Samples were tested for anti-HLA donor-specific antibodies and their characteristics. Antibodies with mean fluorescence intensity > 500 were considered positive.

**Results:** Median time of follow-up of patients was thirty-nine months. Out of nineteen patients with detected donor-specific antibodies, ten patients were identified with immunodominant donor-specific antibodies with C1q-binding capacity (out of them, six patients had anti-HLA donor-specific antibodies detected also before transplantation). C1q-binding antibodies were IgG1 (six patients), IgG3 (three patients) and IgG1 + IgG3 (one patient). Presence at the time of biopsy of donor-specific antibodies and their C1q-binding capacity were independent predictors (HR = 5.13, p < 0.001 and HR = 14.64, p < 0.001; respectively) of inferior kidney graft outcomes (composite of 30% reduction from eGFR at biopsy or death-censored graft loss).

**Conclusion:** Detection of donor-specific antibodies and their C1q-binding capacity might provide prognostic information in post-transplant monitoring in kidney transplant recipients.

**THE IMPACT OF DONOR NEPHRECTOMY ON THE ELDERLY LIVING KIDNEY DONORS**

Takahisa Hiramitsu1, Kenta Futamura2, Manabu Okada2, Goto Norihiko3, Toshihiro Ichimori2, Shunji Narumi2 and Yoshihiko Watarai2

1 Japanese Red Cross Aichi Medical Center Nagoya Daini Hospital, Nagoya, Japan and 2 Japanese Red Cross Aichi Medical Center Nagoya Daini Hospital, Japan

**Background and Aims:** Because of the serious cadaveric donor shortage, the number of living donor kidney transplantation (LDKT) is increasing. To increase the living donor (LD) source, elderly LDs are indicated for the donor nephrectomy. However, the safety of the LDs ≥ 70 years is still remained to be investigated.

**Method:** Between January 2008 and December 2020, a total 1226 LDs for LDKT was included in this retrospective cohort study. LDs were stratified into 3 groups based on age; 244 LDs aged 30–49 years, 803 LDs aged 50–69 years, 179 LDs aged 70–89 years. To investigate the safety of donor nephrectomy in the LDs ≥ 70 years, operative outcomes, the estimated glomerular filtration rate (eGFR) changes, end stage renal disease (ESRD), and mortality were investigated among 3 groups. eGFR changes were analyzed using mixed linear models. The contributing factors for the recovery in the eGFR from the nadir eGFR were analyzed using multivariate linear regression analysis adjusted for mixed linear models. Mortality rates were analyzed using Cox regression models.

**Results:** In the LD characteristics, significant difference was identified in sex. In the operative outcomes, significant difference was not identified in operative duration, blood loss, and complications among 3 groups. In the mixed linear models adjusted for sex, eGFRs of LDs aged 70–89 years were significantly lower at any time points after donor nephrectomy than those in 2 other groups (Figure 1). The eGFR after donor nephrectomy recovers with time in 3 groups. The recoveries in the eGFR from the nadir eGFR were similar among 3 groups. The recoveries in the eGFR were independently affected by the hypertension ($P = 0.008$), smoking history ($P < 0.001$), and body mass index ($P = 0.011$) at donor nephrectomy. Donor age was not the independent factor. The mortality rate of LDs aged 70-89 years was significantly higher than those in 2 other groups (Figure 2). However, during the observational period, ESRD was not identified among 3 groups.

**Conclusion:** eGFR changes and mortality rate were significantly low in LDs aged 70–89 years. However, the recoveries in the eGFR from the nadir eGFR were similar among 3 groups. ESRD was not identified among 3 groups. These results implied that LDs aged 70–89 years might undergo donor nephrectomy safely and complete their lives without ESRD after donor nephrectomy.
Background and Aims: Kidney transplant recipients (KTRs) were advised to tightly adhere to government recommendations to curb the spread of SARS-CoV-2 because of a high risk of morbidity and mortality and decreased immunogenicity after vaccination. The aim of this study was to analyze the change in adherence to preventive measures after vaccination and awareness of antibody response, and to evaluate the effectiveness of these measures.

Method: Questionnaires were sent to 3531 KTRs enrolled in the Dutch RECOVAC studies, retrospectively asking for adherence to nine preventive measures on a 5-point Likert scale before and after SARS-CoV-2 vaccination and after awareness of antibody response. Blood samples were collected 28 days after the second vaccination. Antibody response was categorized as non-responder (≤50 BAU/mL), low-responder (>50 ≤300 BAU/mL) or high-responder (>300 BAU/mL), and shared with participants as a correlate of protection. Adherence before and after vaccination were compared by the Wilcoxon signed rank sum test. Logistic regression analysis was performed to estimate the association between antibody response and adherence, and adherence on acquiring SARS-CoV-2 infection.

Results: In 2939 KTRs (83%) who completed the first questionnaire on adherence to preventive measures, adherence was higher before than after SARS-CoV-2 vaccination (4.56, IQR 4.11-4.78 and 4.22, IQR 3.67-4.67, p < .001) (Figure 1). Adherence after awareness of antibody response was analyzed in 2399 KTRs (82%) of whom also blood samples were available, containing 949 non-responders, 500 low-responders and 950 high-responders. Compared to non-responders, low- and high-responders reported lower adherence (Figure 2). Higher adherence was associated with lower infection rates before and after vaccination (OR 0.67 [0.51-0.91], p = 0.008 and OR 0.48 [0.28–0.86], p = 0.010).

Conclusion: To the best of our knowledge, we are the first to show that KTRs became less adherent to social isolation and other preventive measures after vaccination against COVID-19. Adherence decreased in KTRs who were aware of a subsequent antibody response compared to those without. Moreover, preventive measures in this vulnerable group are effective, regardless of vaccination status.
HUMORAL RESPONSE TO SARS-COV-2 AFTER FIVE SUCCESSIVE DOSES OF mRNA VACCINE AND PASSIVE IMMUNIZATION THERAPY IN STABLE KIDNEY TRANSPLANTATION PATIENTS

Juan Manuel Cazorla López1, Florentino Villanego Fernández2, Aurora Aguilera3, Ana Maria Gomez Romero4, Teresa Trujillo Soto5, Teresa García6, Natalia Montiel1, Cristian Orellana3, Carlos Narváez Mejía4, Manuel Antonio Rodríguez Iglesias5 and Auxiliadora Mazuecos2

1Hospital Puerta del Mar, Nephrology, Spain, 2Hospital Puerta del Mar, Nephrology, Spain and 3Hospital Puerta del Mar, Microbiology, Spain

Background and Aims: The poor humoral response after vaccination against SARS-CoV-2 in kidney transplant recipients (KT) led to the approval of new doses, the fifth being the last administered, and to the development of drugs for passive immunization. Our aim is to analyze the humoral immune response and the evolution of the anti spike (antiS) antibody titer after 5 doses of mRNA vaccine against SARS-CoV-2 and the administration of pre-exposure prophylaxis.

Method: We performed a prospective cohort study of stable KT patients from our center who received 5 doses of an mRNA vaccine from March 2021 to December 2022. KT recipients with less than 6 months after transplantation and with active oncological or hematologic disease were excluded. We determined antiS titers (Abbott SARS-CoV-2 IgG chemiluminescent microparticle immunoassay) at baseline and one month after the second, third, fourth and fifth doses. We consider seroconversion if antiS titer was greater than 260 BAU/mL. We compared humoral response after 2, 3, 4 and 5 doses.

Results: We included 18 KT. Mean age was 59.8 years and 72.2% were male. The median time from KT to the first vaccine dose was 45 months, between the second and third 4 months and 6 months between the third and fourth and fourth and fifth doses. Seroconversion rate was 72% after the fourth and fifth doses. We consider seroconversion if antiS titer was greater than 260 BAU/mL. We compared humoral response after 2, 3, 4 and 5 doses. Seroconversion rate was 11.1% after 2 doses, 50% after 3 doses, 72% after the fourth, and 94.4% after the fifth (p < 0.001). One TR did not develop antibodies after 5 doses. Two KT that had not seroconverted after the fourth also received passive immunization (tixagevimab-cilgavimab), maintaining high antiS titers 3 and 5 months after administration. The KT who seroconverted after 2 doses doubled the antiS titer after the third (1070 vs. 2168 BAU/mL; p = 0.180), in those who seroconverted after 3 doses it increased by 380% after the fourth (802 vs. 2896 BAU/mL; p = 0.028) and in those who seroconverted after 4 doses, the antiS titer increased by 60% (1067 vs. 1762 BAU/mL; p = 0.213). No patients had neither acute rejection nor serious adverse effects.

Conclusion: Successful doses of vaccination increased the development and titer of antibodies against SARS-CoV-2 in KT. However the administration of new doses is necessary, especially bivalent vaccines, which increase protection against new variants of the virus. We should identify those patients who do not generate an adequate humoral response in order to offer them other prevention strategies.

Impact of Mental Illness on Post-transplantation Outcomes in New Zealand: The Asset-Mh Data Linkage Study

Nicole De La Mata1, Nicholas Cross2, Heather Dunkley3, Rachel Cutting4, Ben Beaglehole5, Ian Dittmer5, John Irvine5, Curtis Walker4, Merryn Jones6, Melanie Wylde7, Kate Wyburn8,9 and Angela Webster1,10,11

1University of Sydney, Sydney School of Public Health, Camperdown, Australia, 2Christchurch Hospital, Department of Nephrology, Canterbury District Health Board, Christchurch, New Zealand, 3New Zealand Blood Service, New Zealand Transplantation and Immunogenetics Laboratory, Auckland, New Zealand, 4University of Otago, Dunedin, New Zealand, 5Auckland City Hospital, Auckland, New Zealand, 6Medical Council of New Zealand, Wellington, New Zealand, 7HB District Health Board - Corporate, Hastings, New Zealand, 8Westmead Hospital, Westmead, Australia, 9Royal Prince Alfred Hospital, Camperdown, Australia, 10The University of Sydney, Faculty of Medicine and Health, Camperdown, Australia, 11Westmead Hospital, Department of Renal and Transplant Medicine, Westmead, Australia and 12NHMRC Clinical Trials Centre, Camperdown, Australia

Background and Aims: People with severe mental illness are 6 times more likely to develop kidney disease. Mental illness is overrepresented in the kidney failure population. Up to 40% of dialysis patients are affected by depression and anxiety. There is limited understanding of the extent and impact of mental illness on transplant outcomes. We aimed to evaluate the impact mental illness has upon post-transplant outcomes, including graft failure and death in kidney transplant recipients in New Zealand.

Method: We included all incident kidney transplant recipients in New Zealand, 2006-2019 from the ASSET linked data platform, including Australian and New Zealand Dialysis and Transplant Registry, and national health registries (eg. hospitalisations, prescriptions and mental health services). Presence of mental illness was ascertained based on past use of medications (antipsychotics and antidepressants) and mental health services (community/residential support and inpatient) occurring at least twice over a year. Follow-up was from transplantation until death, graft failure or 31st Dec 2019. We used Cox models to evaluate risk of graft failure or death for mental health users compared to non-mental health users, adjusting for age, sex, calendar year and prior dialysis time.

Results: We included 1,796 kidney transplant recipients, where 457 (25%) had mental illness comorbidity. Overall, 228 (13%) used medication for mental illness (25 antipsychotics; 203 antidepressants) and 340 (19%) used mental health services (327 community/residential support; 14 inpatient). There were 111 recipients (6%) who had used medications and services for mental illness. There were 42 (9%) graft failures and 34 (7%) deaths among those with mental illness compared to 137 (10%) graft failures and 125 (9%) deaths among those without mental illness. Those with mental illness had the same risk of graft failure compared to others (p = 0.17), regardless of whether they used antipsychotics (HR: 1.52, 95%CI: 0.93-2.48, p = 0.09) or received community/residential support (HR: 1.19, 95%CI: 0.78-1.81, p = 0.42). There were no graft failures among those using antipsychotics or receiving inpatient care. Risk of death increased 3-fold (HR: 3.24, 95%CI: 1.51-6.99, p < 0.01) in those using antipsychotics compared to those without mental illness, but was not increased among those using antidepressants (HR: 0.90, 95%CI: 0.47-1.72, p = 0.74). There was weak evidence for an increased risk of death among those receiving community/residential support (HR: 1.57, 95%CI: 0.99-2.49, p = 0.06) compared to those without mental illness. Risk of death was not significantly associated with those receiving inpatient care (HR: 3.00, 95%CI:0.72-12.42, p = 0.13), although event rates were low. For composite of graft failure or death, those with mental illness had the same risk as those without (p > 0.10), regardless of receiving antipsychotics (HR: 1.77, 95%CI: 0.83-3.75) or antidepressants (HR: 1.23, 95%CI: 0.84-1.82), or community/residential support (HR: 1.37, 95%CI: 1.00-1.87) or inpatient care (HR: 1.41, 95%CI: 0.35-5.71).

Conclusion: Mental illness comorbidity is common in this setting, with one in ten transplant recipients in New Zealand receiving psychiatric treatment. Antipsychotic use was associated with three times the risk of death. Otherwise, those with mental illness had comparable post-transplant outcomes. There is opportunity for more collaborative psychiatric and transplant services to promote better patient outcomes and reduce post-transplant mortality.

**Background and Aims:** Tacrolimus is a pivotal maintenance immunosuppressive drug in kidney transplantation (KT). Although diabetogenic property of tacrolimus is still an inevitable concern, it can reduce the risk of acute rejection and improve graft survival compared to cyclosporine. Metformin, despite limited randomized controlled trial, has been found to be safe and effective in patients with post-transplantation diabetes mellitus (PTDM). We aimed to investigate the effect of metformin on acute rejection and graft survival in kidney transplant recipients taking tacrolimus.

**Method:** 442 PTDM patients who were prescribed tacrolimus between 2000 and 2018 were collected. We conducted propensity score matching between the metformin and non-metformin group and evaluated the effects of metformin on the occurrence of T-cell mediated rejection (TCMR) and antibody-mediated rejection (ABMR), and graft survival with Cox proportional hazard model.

**Results:** During the average follow up of 8.7 years, 90 patients were diagnosed as PTDM within one year after KT. Among 442 patients taking tacrolimus, 297 patients were treated with metformin for the average of 4.4 years. After 1:1 matching, cumulative incidences of TCMR (p = 0.008) and graft failure (p = 0.005) in the metformin group was lower than the non-metformin group, while no significant difference was observed in ABMR. Metformin use was associated with a reduced risk of TCMR (HR 0.43, 95% CI 0.21-0.88, p = 0.021) and graft failure (HR 0.39, 95% CI 0.19-0.79, p = 0.009). There was no significant difference in t (tubulitis), i (interstitial inflammation), and v (endarteritis) scores of TCMR between the metformin and the non-metformin group.

**Conclusion:** Our study demonstrates that combination therapy with metformin and tacrolimus in kidney transplant recipients with PTDM is associated with a lower risk of acute rejection and graft failure.

**Background and Aims:** The prevalence of post-COVID-19 condition (PCC) is estimated to be 13% in healthy individuals. We analyzed the prevalence and disease burden of PCC in patients with chronic kidney disease (CKD) G4/5, dialysis patients and kidney transplant recipients (KTR).

**Method:** Patients participated in the RECOVAC study, in which SARS-CoV-2 antibodies were measured in CKD G4/5, dialysis patients and KTR after the second and third COVID-19 vaccination in the Netherlands. A questionnaire was sent to 4868 participants one year after initial vaccination asking for the presence of long-lasting symptoms after diagnosis in COVID-19 positive patients, or since the start of the pandemic in COVID-19 negative patients. PCC was defined according to the WHO clinical case definition. Blood samples at one month after the second and third vaccination were analysed with anti-RBD IgG ELISA. COVID-19 diagnosis was assessed by questionnaire and antibody analysis. Logistic regression analysis was used to compare the presence of one or more long-lasting symptoms between COVID-19 positive and negative patients. In COVID-19 positive patients, we likewise identified predictors of PCC by backward selection and estimated the association between log-transformed antibody levels and PCC.

**Results:** 2747 patients were included, of which 222 patients with CKD G4/5, 390 dialysis patients and 2135 KTR. PCC was present in 25%, 16%, and 21% of CKD G4/5 patients, dialysis patients and KTR with high or very...
high symptom burden in 57%, 61% and 71%, respectively. In COVID-19 negative patients, long-lasting symptoms were present in 15%, 13% and 18%, respectively. COVID-19 positive patients (n = 1004) were at higher odds of having one or more long-lasting symptoms compared with COVID-19 negative patients (n = 1743) (OR: 1.33 [1.09–1.61], p = .005). Predictors of PCC were chronic lung disease (adjusted OR 2.04 [1.18–3.50], p = .01) and hospital/ICU admission (adjusted OR 5.03 [3.22-7.86], p < .001). Log anti-RBD IgG antibody level was negatively associated with PCC (adjusted OR: 0.79 [0.66–0.94], p = .008).

Conclusion: Patients with CKD G4/5, dialysis patients and KTR are at risk for PCC with a high symptom burden, especially if antibody levels after COVID-19 vaccination are low.

GRADES II-III INTRA-ABDOMINAL HYPERTENSION INCREASE THE RISK OF GRAFT LOSS OR DEATH AFTER KIDNEY TRANSPLANTATION

Paula Ardura1, María Martínez Manrique1, Isabel Acosta-Ochoa1, Raquel Gordillo3, Sandra Sanz-Ballesteros1, Ana Lucía Valencia Peláez1, Arturo Lorenzo2, Veronica Fidalgo3, Alicia Mendiluce1 and Armando Coca1

1Hospital Clínico Universitario de Valladolid, Nephrology, Valladolid, Spain, 2Hospital Río Carrión, Nephrology, Palencia, Spain and 3Complejo Asistencial de Zamora, Zamora, Spain

Background and Aims: Intra-abdominal hypertension (IAH) is common among post-surgical, critically ill and kidney transplant patients, and is associated with acute kidney injury and increased morbidity and mortality. We aimed to describe the medium-term effect of IAH on graft and patient survival after deceased-donor kidney transplantation.

Method: 192 consecutive patients who received a cadaveric renal allograft transplant at our hospital were included in this study. IAP was measured every 8h for at least the first 72h after surgery using the urinary bladder technique, and an average value was obtained. Patients were followed up for 24 months or until a composite outcome (defined as graft loss or recipient death) occurred. Clinical, anthropometric, and analytical data was extracted from our hospital’s database. Statistical analysis was performed using IBM SPSS Statistics 22. The study was approved by the local ethics committee.

Results: 192 patients were included. Relevant clinical and anthropometric data are summarized in Table 1. Patients with grades II or III IAH were more frequently male, had longer dialysis vintage, received more frequently hemodialysis as renal replacement therapy and suffered delayed graft function, graft loss or death more repeatedly. In Kaplan-Meier analysis, grade II IAH or higher were associated with lower composite-outcome free survival (Log-Rank: 8.053; p = 0.018) (Figure 1).

Conclusion: Grade II-III IAH appear to be a risk factor for graft loss or recipient death in our sample of deceased donor kidney transplant recipients. Monitoring of intra-abdominal hypertension could provide useful information to identify patients at higher risk of post-transplant complications.

Table 1: Clinical and anthropometric data.

DEVELOPMENT, APPLICATION, AND VALIDATION OF A HISTOLOGICAL CLASSIFICATION AUTOMATION SYSTEM FOR KIDNEY ALLOGRAFT PRECISION DIAGNOSTICS

Daniel Yoo1, Valentin Goutaudier1, Gillian Divard1, Juliette Gueguen1, Olivier Aubert1, Marc Raynaud1, Zeynep Demir1, Julien Hogan1, Ktd-Innov Investigators3, Eu-Train Investigators4, Mark Haas5, Carmen Lefaucheur1, Marion Rabant1 and Alexandre Loupy1

2Néphrologie-Immunologie Clinique, Hôpital Bretonneau, CHU Tours, Tours, France, Tours, France, 3KTD-Innov Consortium, France and 4Comprehensive Transplant Center, Cedars-Sinai Medical Center, Los Angeles, CA, USA, Los Angeles, United States of America

Background and Aims: The Banff histological classification is the gold standard for allograft rejection diagnostics but has become considerably more complex over the past three decades, leading to misclassifications. We aimed to develop an automated rejection classification system and demonstrate its ability to improve rejection diagnoses.

Method: We built a consortium consisting of pathologists, physicians, and developers to translate all Banff classification rules until the latest version published in 2019 into an algorithm, further embedded in an application which automatically assigns diagnoses. We then tested the Banff Automation System's ability to reclassify rejection diagnoses on 4,409 kidney transplant biopsies from 3,054 adult and pediatric patients, from multicenter cohorts and clinical trials, totaling 20 transplant referral centers in Europe and North America. The impact of diagnostic reclassifications on graft survival was evaluated.

Results: We devised a system that generates automatic reports with diagnoses and a decision tree. In the adult kidney transplant biopsies, the Banff Automation System reclassified 83 of 279 (29.75%) antibody-mediated rejection (AMR) cases and 57 of 105 (54.29%) T-cell mediated rejection (TCMR) cases, while 237 of 3,239 (7.32%) biopsies with non-rejection-related diagnoses were reclassified as rejection. The rejection reclassification rates were 8 of 26 (30.77%) and 12 of 39 (30.77%) for AMR and TCMR, respectively, in the pediatric cohort. Finally, we found that the non-rejection diagnoses according to the pathologists which were reclassified as rejections by the Banff Automation System had similar outcomes as those of confirmed rejection cases.

Conclusion: We built the first comprehensive Banff Automation System and confirmed its ability to reclassify rejection diagnoses. This decision support system might help for training and standardizing diagnoses in routine care and clinical trials.

Figure 1: Sankey diagram representing diagnostic reclassifications by the Banff Automation System.

SARCOPENIA AS A PREDICTOR OF MORTALITY IN KIDNEY TRANSPLANT RECIPIENTS

Akihiro Kosoku1,2, Tamoaki Iwai2, Kazuya Kabei2, Shunji Nishide1, Yuichi Machida2 and Junji Uchida2

1Meijibashi Hospital, Urology, Matsubara, Japan, 2Osaka Metropolitan University Graduate School of Medicine, Urology, Osaka, Japan and 3Osaka City General Hospital, Urology, Osaka, Japan

Background and Aims: Sarcopenia is a risk factor for adverse outcomes in older adults and dialysis patients, but this has yet to be confirmed in kidney transplant recipients. This study aimed to investigate the association of sarcopenia with all-cause mortality in kidney transplant recipients.

Method: In this single-center prospective cohort study, kidney transplant recipients were evaluated at baseline muscle mass, muscle strength, and physical performance using a hand dynamometer, 10-m walk test, and bioelectrical impedance analysis, respectively. Sarcopenia was defined according to the Asia Working Group for Sarcopenia 2019 criteria. Propensity score matching was used to reduce bias between the sarcopenia and non-sarcopenia groups, adjusted for three potential confounding variables including age, sex, and body mass index. After a 5-year follow-up, patient survival was assessed by the Kaplan-Meier method and Cox proportional hazards model in the matched cohort.

Results: Out of 212 patients (median age, 54 years; median transplant vintage, 79 months) enrolled in this study, patients who had sarcopenia at baseline was 33 (16%). After 1:1 propensity score matching, a matched cohort with 62 patients was generated. In the matched cohort, the overall incidence density rates of mortality were 48.8 and 6.75 per 1000 person-years in the sarcopenia and non-sarcopenia groups, respectively. The survival curves estimated using the Kaplan-Meier method indicated that the sarcopenia group was significantly lower cumulative survival than the non-sarcopenia group (log-rank test, p = 0.025). Moreover, the sarcopenia group had a significantly higher mortality risk than the non-sarcopenia group (hazard ratio = 7.59, 95% confidence interval = 1.93–61.7).

Conclusion: Sarcopenia was a significant predictor of mortality in kidney transplant recipients.

MAJOR HLA ALLELE AND HAPLOTYPE FREQUENCIES IN THE MALTESE KIDNEY TRANSPLANT REGISTRY
Sarah Micallef and Jesmar Buttigieg
Mater Dei Hospital, Department of Nephrology, Malta

**Background and Aims:** The human leukocyte antigens (HLA) are the most diverse and polymorphic genes in the human genome and matching them is of vital importance for maximising the survival of kidney transplants. The Maltese archipelago consists of three inhabited islands in the Mediterranean Sea, with a total population of just over half a million people. HLA polymorphisms in Malta have never been described. The aim of this study was to investigate allelic frequencies and determine the most common haplotypes for major HLA Class I and Class II groups in the Maltese kidney transplant registry. This will hopefully facilitate organ sharing with other European countries and improve the HLA matching for kidney transplant recipients.

**Method:** All patients of Maltese ethnicity on the national kidney transplant list between 2018 and 2022 were analysed retrospectively. HLA typing is routinely performed at medium to high resolution using polymerase chain reaction sequence specific oligonucleotide probes and Luminex technology at the HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ and HLA-DP loci. Allele and haplotype frequencies were calculated by direct counting and simple percentages.

**Results:** A total of 191 patient samples were analysed yielding the following allele types: 16 HLA-A, 31 HLA-B, 17 HLA-C, 15 HLA-DRB1, 6 HLA-DP, 7 HLA-DQ, 5 HLA-DRB3, one HLA-DRB4 and one HLA DRB5. The most frequent allele groups for the HLA-A locus were HLA-A*02 (30.9%), HLA-A*24 (12.0%) and HLA-A*01 (11.8%) whilst for the HLA-B locus these were HLA-B*35 (16.2%), HLA-B*18 (11.5%) and HLA-B*51 (7.1%). The most prevalent allele groups for the HLA-DRB1 locus were HLA-DRB1*11 (24.1%), HLA-DRB1*04 (13.1%) and HLA-DRB1*07 (11.3%). The commonest allele group for each of HLA-C, HLA-DP and HLA-DR loci were HLA-C*07 (23.6%), HLA-DP4 (5.8%), HLA-DQ7 (31.2%) respectively. The five most frequently encountered haplotypes were HLA-A*02-B*13-DRB1*07 (2.1%), HLA-A*02-B*35-DRB1*04 (1.6%), HLA-A*02-B*18-DRB1*10 (1.3%), HLA-A*02-B*35-DRB1*11 (1.3%), HLA-A*24-B*35-DRB1*11 (1.3%).

**Conclusion:** This study provides the first data on the Major HLA allele and haplotype frequencies in Maltese kidney transplant candidates. Such data may be crucial in setting up international kidney exchange programmes.

A COMPARATIVE ANALYSIS OF EMOTIONAL RECOGNITION AND DIFFERENTIATION TWO YEARS FOLLOWING KIDNEY TRANSPLANTATION VERSUS HEMODIALYSIS.
Emad Samaan1, Rabab Elrefaey1, Mahmoud Sobh1, Youssef Abulatta2, Ibthail Ibrahim3, Mohamed Sobh4 and Eman Nagy1
1Mansoura Nephrology and Dialysis Unit, Faculty of Medicine, Mansoura University, Mansoura, Egypt, Mansoura, Egypt, 2Mansoura University, Medical Inten- Mansoura University Hospitals, Mansoura, Egypt, 3Mansoura University, Psychiatry, Mansoura, Egypt and 4Urology and Nephrology center, Mansoura Faculty of Medicine, Mansoura, Egypt

**Background and Aims:** Cognitive impairment is common in patients with End Stage Kidney Disease. There are conflicting reports regarding the degree and interval of improvement of cognitive functions with the different modalities of renal replacement therapy. Most of the published reports relied on screening tests not covering the emotional aspects of cognition. Also, the timings of assessment are different being at most during the first year of establishing the modality.

**Method:** Ninety age, gender, and educational level-matched participants were enrolled in the study. The participants were divided into three equal groups, thirty kidney transplant (KT) patients, thirty hemodialysis patients (HD) for more than two years, and thirty control non-diseased participants. The participants included were below 60 years of age and with no previous history of a neurological defect. All patients were subjected to three Computerized Neurocognitive Battery tests (Age differentiation test, emotional recognition, and differentiation). All the tests were judged for accuracy and the time consumed to answer.

**Results:** The median value of transplant duration was 59 months (24-168), and 66 months (27-180) of HD duration. Both groups were comparable in age, gender, educational level, socioeconomic, and marital status. KT patients were comparable to controls at all parameters of testing. KT patients’ answers were significant of higher accuracy than HD patients (P = 0.04 for age differentiation and emotion recognition, and 0.005 for emotion differentiation). KT and HD had comparable response times. Total correct responses of emotional differentiation tests were negatively correlated with KT duration (rho = −0.348, P = 0.02), and (rho = −0.345, P = 0.01) for HD duration. The cumulative steroid dose was not correlated with any of the tested parameters in the KT group.

**Conclusion:** KT offers a much better emotional and social cognitive improvement, an effect that is expected to positively impact the quality of life and involvement in society.

PREDICTION OF GRAFT SURVIVAL PRIOR TO ACCEPTING AN OFFER FOR LIVING DONOR KIDNEY TRANSPLANT: AN ARTIFICIAL INTELLIGENCE APPROACH
Hatem Kaies Ibrahim Elsayed Ali1,2, Bernard Burke1, Mahmoud Mohamed1, David Briggs3 and Nithya Krishnan1,2
1University Hospitals of Coventry and Warwickshire, renal department, UHCW, Coventry, United Kingdom, 2Coventry University, Research Centre for Sport, Exercise and Life Sciences, United Kingdom, 3University of Mississippi, United States of America and 4NHSBT, United Kingdom

Background and Aims: The current available models for evaluation of outcomes of living donor kidney transplant before accepting an offer are poorly developed, reported, validated and have small sample sizes. We aim to use Artificial Intelligence to build a model that can accurately predict death censored graft survival for living donor kidney transplant prior to accepting an offer.

Method: All living kidney transplant patients who were registered in the UNOS database between 1/1/2007 and 1/6/2021, maintained on TAC/MMF immunotherapy were included in our analysis. We excluded patients with age<18 years old and ABO incompatible transplant. We divided the data randomly into training and testing dataset with ratio 80:20. We performed recursive feature elimination to select the important ones for prediction. Features were selected based on their Gini impurity scores. We performed Artificial Neural Network analysis (ANN). We evaluated the model using Harrell Concordance-time-dependent score (for discrimination), and Integrated Brier score (for calibration). We also assessed dynamic AUC for model performance.

Results: 154,110 living donor kidney transplant patients were included in our study. Harrell C-Statistic scores were 0.50 at 5 years post-transplant, 0.68 at 10 years post-transplant and 0.68 at 10 years post-transplant, indicating very high discrimination power. Integrated Brier Score was 0.08, indicating very high calibration score for our model. Dynamic AUC scores were 0.71 at 5 years post-transplant and 0.68 at 10- and 13-years post-transplant, indicating adequate performance for our model. The key players in our model were recipient age (variable importance = 0.26), donor age (variable importance = 0.17), donor ethnicity (variable importance = 0.90), followed by dialysis vintage pre-transplantation.

Conclusion: The ANN model had high discrimination, calibration, and performance indices for predicting death censored graft survival prior to transplant. It can aid the clinical decision for management of the transplant patients. We are currently developing a user-friendly web application that can be used to apply the ANN model for prediction. Our model can help ranking potential living kidney donors based on graft outcomes. Therefore, our model can help improve current outcomes of kidney paired exchange schemes.

Method: We used data from stable KTRs ≥1 year after transplantation who participated in the TransplantLines Food and Nutrition Cohort study. Plasma cadmium and iron status parameters, i.e., ferritin, iron, and transferrin saturation (TSAT), were measured at baseline. ID was defined as TSAT<20% and ferritin <300 μg/L. Linear regression analyses were applied to study the association between iron status parameters and cadmium levels. Multivariable Cox regression analyses were used to investigate the association of plasma cadmium levels with all-cause mortality, adjusted for age, sex, BMI, smoking status, history of cardiovascular disease, glucose, HbA1c, systolic blood pressure, eGFR, cholesterol, and ID at baseline. In sensitivity analyses, we repeated these analyses using an alternative definition of ID, TSAT<20% and ferritin<100 μg/L (IDalt).

Results: We included 670 KTRs (age 53±13 years, 58% males, median 5.4 (IQR, 1.9-11.7) years after transplantation). KTRs with ID (30% of all KTRs, median plasma cadmium level 63 (IQR. 48-76) ng/L) had higher cadmium levels than KTRs without ID (median 56 (IQR. 42-75) ng/L, P = 0.01, Figure 1). ID was not associated with plasma cadmium after adjustment for age, sex, and smoking status. However, within the ID group, TSAT (β = -0.016, P = 0.01) and serum iron (β = -0.023, P = 0.01) were inversely associated with log-transformed cadmium levels, independently of age, sex, and smoking status. Sensitivity analysis yielded similar results: KTRs with ID (23% of all KTRs) had higher cadmium levels than KTRs without ID (median 61 (IQR. 49-76) ng/L vs median 57 (IQR. 42-75) ng/L, P = 0.03). Furthermore, in Cox regression analysis, KTRs in the highest tertile of plasma cadmium levels (70 ng/L to 330 ng/L) had an increased risk of mortality (hazard ratio 2.80, 95%CI 1.47-5.36, P = 0.01) compared to KTRs in the lowest cadmium tertile (19 ng/L to 48 ng/L) during a median follow-up of 4.9 (IQR. 3.5-5.5) years. No significant interaction by iron status was observed for the association between plasma cadmium and mortality.

Conclusion: KTRs with ID had higher cadmium levels than KTRs without ID, and higher plasma cadmium levels were independently associated with a higher mortality risk. The association of cadmium with mortality was not different between individuals with and without ID at baseline. Further investigations should determine whether ID correction prevents cadmium accumulation in KTRs.

IRON DEFICIENCY AND CADMIUM LEVELS IN KIDNEY TRANSPLANT RECIPIENTS
Pien Rawee, Daan Kremer, Daan Touw, Martin de Borst, Stephan J.L. Bakker and Michele Eisenga
University Medical Center Groningen, Netherlands

Background and Aims: A higher plasma level of cadmium, a nephrotoxic divalent heavy metal, has been associated with an increased risk of graft failure in kidney transplant recipients (KTRs). The drivers of cadmium toxicity in KTRs are incompletely understood. We hypothesize that iron deficiency (ID) increases cadmium absorption and accumulation by upregulation of divalent metal transporters. Here, we first investigated whether ID is associated with higher plasma cadmium levels. As increased cadmium levels have previously been associated with cancer, cardiovascular disease, and diabetes in other populations, we also examined whether plasma cadmium levels are associated with all-cause mortality in KTRs.

Method: We used data from stable KTRs ≥1 year after transplantation who participated in the TransplantLines Food and Nutrition Cohort study. Plasma cadmium and iron status parameters, i.e., ferritin, iron, and transferrin saturation (TSAT), were measured at baseline. ID was defined as TSAT<20% and ferritin <300 μg/L. Linear regression analyses were applied to study the association between iron status parameters and cadmium levels. Multivariable Cox regression analyses were used to investigate the association of plasma cadmium levels with all-cause mortality, adjusted for age, sex, BMI, smoking status, history of cardiovascular disease, glucose, HbA1c, systolic blood pressure, eGFR, cholesterol, and ID at baseline. In sensitivity analyses, we repeated these analyses using an alternative definition of ID, TSAT<20% and ferritin<100 μg/L (IDalt).

Results: We included 670 KTRs (age 53±13 years, 58% males, median 5.4 (IQR, 1.9-11.7) years after transplantation). KTRs with ID (30% of all KTRs, median plasma cadmium level 63 (IQR. 48-76) ng/L) had higher cadmium levels than KTRs without ID (median 56 (IQR. 42-75) ng/L, P = 0.01, Figure 1). ID was not associated with plasma cadmium after adjustment for age, sex, and smoking status. However, within the ID group, TSAT (β = -0.016, P = 0.01) and serum iron (β = -0.023, P = 0.01) were inversely associated with log-transformed cadmium levels, independently of age, sex, and smoking status. Sensitivity analysis yielded similar results: KTRs with ID (23% of all KTRs) had higher cadmium levels than KTRs without ID (median 61 (IQR. 49-76) ng/L vs median 57 (IQR. 42-75) ng/L, P = 0.03). Furthermore, in Cox regression analysis, KTRs in the highest tertile of plasma cadmium levels (70 ng/L to 330 ng/L) had an increased risk of mortality (hazard ratio 2.80, 95%CI 1.47-5.36, P = 0.01) compared to KTRs in the lowest cadmium tertile (19 ng/L to 48 ng/L) during a median follow-up of 4.9 (IQR. 3.5-5.5) years. No significant interaction by iron status was observed for the association between plasma cadmium and mortality.

Conclusion: KTRs with ID had higher cadmium levels than KTRs without ID, and higher plasma cadmium levels were independently associated with a higher mortality risk. The association of cadmium with mortality was not different between individuals with and without ID at baseline. Further investigations should determine whether ID correction prevents cadmium accumulation in KTRs.

PATIENT OUTCOMES AND DYNAMICS OF THE AUSTRALIAN KIDNEY TRANSPLANT WAITLIST: SUSPENSIONS, RETURNING TO WAITLIST, TRANSPLANTATION AND DEATHS

Nicole De La Mata¹, Victor Khoul¹, James Hedley¹, Brenda Rosales¹, Rachael Morton² and Angela Webster¹,²

¹The University of Sydney, Sydney School of Public Health, Camperdown, Australia and ²NHMRC Clinical Trials Centre, Camperdown, Australia

Background and Aims: People on the kidney waitlist are less informed about potential temporary or permanent suspensions. Disparities may exist among those who are suspended and who return to the waitlist. In Australia, average wait times vary by state/territory and blood group, but overall is X years. We aimed to describe and evaluate factors associated with waitlist transitions and subsequent outcomes after entering the waitlist for deceased donor kidney transplant.

Method: We included all incident patients waitlisted for their first transplant from deceased donors in Australia during 2006-2019. We described all clinical transitions after entering the kidney waitlist including: active on waitlist; suspended; kidney transplant; graft failure; and death. We predicted the restricted mean survival time from waitlist entry until first transplant with 5 year time horizon and summarized the annual percentages in each clinical state until 5 years. We used flexible parametric multi-state survival models to evaluate factors associated with transitions after entering the waitlist until first transplant, reporting the hazard ratio (HR) for each transition. We used Cox proportional hazards models to evaluate factors associated with death while waiting and first transplant, reporting HR for these outcomes.

Results: Of 8,466 people who entered the kidney waitlist, 6,741 people received their first transplant (6,163 deceased donor; 506 living donor; 99 paired kidney exchange donors), 381 people died while waiting (31 active on waitlist; 350 suspended) and 1,344 were still waiting for a transplant (844 active on waitlist; 500 suspended). Nearly two-thirds (63%) were not suspended while waiting, but 2,111 (25%) were suspended once and 1,016 (12%) were suspended ≥2 times. Of those suspended, 47% spent a total of <6 months off-waitlist. Predicted mean time from waitlist entry to transplant increased with number of suspensions, from 1.9 years (95% CI:1.8-1.9 years) in patients not suspended to 3.0 years (95% CI:2.8-3.2 years) in patients suspended once or more. For the entire cohort, the 1-year probability of transplant was 41%(95%CI:40-42%),

Figure 1: Annual percentages after entering kidney waitlist in Australia, 2006-2019.
Factors associated with transitions and clinical endpoints after entering kidney waitlist.

At 5 years, the active on waitlist was 42% (95% CI: 41-43%), suspended was 11% (95% CI: 10-12%) and death was 1.4% (95% CI: 1.2-1.7%) (Fig. 1). At 5 years, this increased to 63% (95% CI: 62-64%) transplanted, 5% (95% CI:4-5%) active on waitlist, 10% (95% CI:9-11%) suspended and 13% (95% CI:12-14%) died. Several patient factors were associated being suspended and returning to the waitlist, as well as with receiving transplant and death while waiting (Fig. 2). Having been suspended from the waitlist, increased the likelihood of further suspensions by 4.2 times (95% CI: 3.8-4.6; p < 0.001) and returning to the waitlist by 50% (95% CI: 36-65%; p < 0.001) but decreased the likelihood of receiving a transplant by 29% (95% CI: 62-82%; p < 0.001). Being previously suspended once reduced the risk of death while waiting by 31% (HR: 0.69, 95% CI: 0.52-0.91; p < 0.01), likely a paradox of being well enough to return to the waitlist at least once. Socio-demographic factors were modifiers of returning to the waitlist after suspension. Males of Australian or New Zealand ethnicity (non-Indigenous) were 13% (95% CI: 4-23%) more likely to return to the waitlist compared to females of the same ethnicity (p = 0.01). However, males of Aboriginal, Torres Strait Islander, Māori or Pacific Islander ethnicity had the same likelihood of returning to the waitlist as their female counterparts (p = 0.08).

Conclusion: The dynamics of the transplant waiting list were not straightforward. About one-third of patients were suspended at least once and wait 1 year longer for a transplant compared with those not suspended. Our findings will provide evidence to support more informed discussions about the patient journey from waitlist to transplantation, and aid in shared decision making.

MAGNETIC RESONANCE RADIOMIC ANALYSIS FOR THE PREDICTION OF GRAFT FAILURE IN PATIENTS WITH KIDNEY TRANSPLANTATION
Francesco Fontana¹, Gaetano Alfano¹, Filippo Monelli², Giulia Besutti², Valeria Trojani² and Gabriele Donati¹
¹Azienda Ospedaliero Universitaria di Modena, Modena, Italy and ²Azienda AUSL-IRCCS di Reggio Emilia, Italy

Background and Aims: Prediction of future graft failure with non-invasive investigations is a relevant objective for transplant clinicians. We previously demonstrated a promising discrimination capacity for interstitial fibrosis / tubular atrophy (IFTA) >50% in kidney biopsy of a machine learning (ML) based magnetic resonance imaging (MRI) radiomic algorithm. Aim of the present study is to evaluate accuracy of MRI radiomic-based ML algorithms in predicting future graft failure.

Method: Single-center retrospective observational cohort study on a previously characterized cohort of kidney transplant recipients who underwent graft biopsy and graft MRI imaging within 6 months from biopsy, both on clinical indication, at the “Azienda Ospedaliero-Universitaria di Modena”, Italy, from 1/1/2012 to 1/3/2021. The primary outcome was to identify the best combination of MRI radiomic features for the prediction of graft failure during follow-up. Segmentation of renal parenchyma, cortex and medulla on MRI sequences was performed using the 3DSlicer software. Radiomic features were then extracted using an in-house software based on pyradiomics applying Wavelet and Gaussian filters. LASSO algorithm was employed to select correlated features with outcome and summarize them in a radiomic signature. Using radiomic signature alone and then merged with meaningful clinical data we trained ML-algorithms using 70% of cases for training/validation, with a 10-fold internal cross-validation, and 30% for model testing. Model performance was assessed using AUC with a 95% confidence interval (CI).

Results: Seventy coupled tests (63 patients) were included and randomly subdivided into a training/validation cohort (n = 50) and a test cohort (n = 20). Median follow-up was 24.73 months (interquartile range 13.64-46.57). Radiomic model had an AUC of 0.88 (95% CI 0.70-0.97) in training and 0.57 (95% CI 0.23-0.86) in test cohort. Radiomic-clinical mixed model had an AUC of 0.90 (95% CI 0.73-0.98) in training and 0.66 (95% CI 0.33-0.88) in test cohort.

Conclusion: We produced an MRI radiomic-based ML algorithm with good prediction ability for future graft failure in patients with kidney transplant. Given the limited number of enrolled patients, validation in larger (and ideally prospective) cohorts is required to confirm our findings. Comparison of radiomic-based ML with histological parameters (i.e., IFTA) for the prediction of graft failure in our cohort is currently under assessment.
MEASURING CLINICAL JUDGEMENT IN PROSPECTIVE KIDNEY TRANSPLANT RECIPIENTS: A FEASIBILITY STUDY
Jennifer Lees1, Duncan Jackson2, Michael Sullivan3, Karen Stevenson3, Kate Stevens3, Jan Hunter4, Jill Park4, William Norton4, Jake Lever4, Frances Mair1 and David McAllister1

1University of Glasgow, United Kingdom, 2King’s College London, United Kingdom and 3NHS Greater Glasgow and Clyde, United Kingdom

Background and Aims: Exercising clinical judgement is becoming more challenging in the context of ageing populations, increasing prevalence of multimorbidity and frailty, and insufficient evidence regarding how best to manage increasing complexity in clinical practice. Measures of clinical judgement are surprisingly absent from health information systems despite their clear importance and the potential costs of poor decisions. Suitability for kidney transplantation is a high-stake clinical judgement, requiring consideration of complex biopsychosocial patient and organ-utilisation factors. This study aimed to test if it is feasible to assess clinical judgement quantitatively from routine clinical documentation in kidney transplant recipients.

Method: Participants were identified from a regional register of patients on haemodialysis, who underwent deceased donor kidney transplantation (KTR) and had at least 1 year of follow-up. We identified 15 KTR who had poor outcomes, defined as more than 6 hospital admissions or death within one-year of transplantation. Fifteen KTR controls were matched using the United Kingdom Renal Recipient Index (UKRRI: a composite score of age, dialysis requirement at listing, wait time on dialysis and diabetes status). Six blinded raters (two nephrologists, two transplant surgeons and two kidney transplant coordinators) scored clinical letters written at the time of transplant assessment across four domains (Clinician Belief of Appropriateness [CBA] for perceived suitability, perceived benefit, predicted short-term harm, predicted long-term harm: from 1 = worst, to 5 = best). The total CBA score was calculated as the mean score across the 4 domains. CBA scores were compared between raters using the intra-class correlation coefficient (ICC: for two-way agreement). Logistic regression models tested odds of poor outcome by CBA scores across 4 domains.

Results: Practicing clinicians were eager to participate, suggesting this type of research will be worthwhile and feasible. Among 30 KTR, the median total CBA transplant suitability score was 3 (IQR 3-4, range 1-5). Overall agreement was moderate (ICC for the total CBA score: 0.63, 95% CI 0.51-0.74; p < 0.001), but with substantial variation in CBA scores across the domains and between raters (Figure 1). In 3 of the 4 domains (perceived suitability: OR 0.91, 95% CI 0.48-1.73; predicted short-term: OR 0.70, 95% CI 0.33-1.51; and predicted long-term harms: OR 0.82, 95% CI 0.35-1.91), CBA scores adjusted for UKRRI were associated with poor outcome after transplantation in the expected direction. For predicted benefit, the point estimate was not in the expected direction; individuals with greater predicted benefits were more likely to have poor outcomes (OR 1.46, 95% CI 0.28-7.47). Unsurprisingly, given the small numbers in this pilot and the substantial influence of the donor organ on outcomes in kidney transplantation, all the confidence intervals were wide and crossed the null, indicating considerable uncertainty.

Conclusion: In patients undergoing assessment for kidney transplantation, measuring clinical judgement retrospectively is feasible, though subject to variability across domains and between raters. We did not identify any clear associations between retrospective assessment of CBA and outcome after kidney transplantation in this small pilot. In future work, we will develop and validate measures of clinical judgement, collect these measures prospectively, and examine the relationship of measured clinical judgement with health outcomes.

E3 - TREATMENT & CLINICAL TRIALS

USE OF GLUCAGON-LIKE PEPTIDE 1 RECEPTOR AGONISTS IN KIDNEY TRANSPLANT PATIENTS: A MULTI-CENTER STUDY
Luis Alberto Vigara Sánchez1, Florentino Villanegó Fernández2, Cristhian Orellana2, Myriam Eady Alonso2, María Gabriela Sánchez Márquez1, María Belén García Jiménez2, Marta Alonso1, Jose Manuel Amaro1, Teresa García1 and Auxiliadora Mazuecos2

1Jerez de la Frontera University Hospital, Department of Nephrology, Jerez de la Frontera (Cádiz), Spain, 2Puerta del Mar University Hospital, Department of Nephrology, Cádiz, Spain and 3Puerto Real University Hospital, Department of Nephrology, Puerto Real (Cádiz), Spain

Background and Aims: Diabetes mellitus (DM) is a frequent complication in kidney transplant (KT) patients, leading to a higher cardiovascular mortality and graft loss. The use of therapies such as Glucagon-like peptide-1 receptor agonist (GLP-1RA) could have benefits in KT, although the experience reported so far is limited. The aim of our study is to describe the effectiveness and safety of GLP-1RA in KT patients.

Method: Retrospective cohort study of KT with DM who started GLP-1RA in three Spanish hospitals (Puerta del Mar University Hospital, Jerez de la Frontera University Hospital and Puerto Real University Hospital) from February 2016 to July 2022. All patients had a minimum follow-up of 6 months after starting the treatment. Clinical and demographic variables were analyzed. We collected GLP-1RA type and dose. Glomerular filtration rate (eGFR), proteinuria, and weight were collected at the start of treatment and after 6 and 12 months. We analyze glycemic control, blood pressure and lipid profile. Acute rejections (AR), de novo donor-specific antibodies (DSA) and adverse effects were documented. Parametric and non-parametric tests were performed according to the normality of the sample.

Figure 1: Alluvial plot of differences in transplant suitability (CBA) scores across 4 domains, stratified by rater type.
Results: In this period, 102 KT with DM were treated with GLP-IRA from 19/02/2016 to 22/07/2022. At the time of the prescription mean body mass index was 35.8 kg/m² and the mean weight was 95 kg. Forty-two (44%) had developed post-transplant diabetes mellitus (PTDM). The mean age was 62 years and 56% were men. Mean baseline estimated glomerular filtration rate (eGFR) was 47.2 ml min/1.73 m² and the time post-KT was 47 months. The GLP-IRA mostly prescribed was semaglutide (66.7%). Fifty-five (55%) patients reached the maximum recommended dose of the drug. The maintenance immunosuppressive therapy used was steroids (94.7%), tacrolimus (97.4%), mycophenolate (94.7%) and everolimus (2.6%). Eighty-four KT recipients had a minimum follow-up of 6 months and sixty-four were followed for 12 months. We observed stability in eGFR and a reduction in proteinuria (−19.1 mg/g at 6 months, p = .000 and −3.6 Kg at 12 months, p = .000). Furthermore, Hba1c decreased (−1.2 mmol/L at 6 months, p = .000 and −1.5 mmol/L at 12 months, p = .000). Notably, insulin dose was also reduced (−2.2 UI/day at 6 months, p = .048) but the number of patients with sodium-glucose cotransporter 2 inhibitors increased at 12 months (p = 0.031). Finally, we observed a reduction in total cholesterol (−11.5 mg/dL at 6 months, p = .001 and −15.6 mg/dL at 12 months p = .000) and LDL-c (−9.2 mg/dL at 6 months, p = .002 and −16.8 mg/dL at 12 months, p = .000) during the follow-up. However, patients receiving statins and steroids and the dose remained unchanged. Fifteen patients (14.7%) suffered from side effects, mainly nausea and vomiting, and ten patients (9.8%) discontinued the treatment for this reason. No changes in the mycophenolate formulation were made. One patient discontinued the treatment due to the diagnosis of pancreatic cancer 8 months after starting the drug. We did not find differences in the levels in the dose of tacrolimus. Neither AR episodes nor de novo DSAs development were notified.

Conclusion: This is the first multicenter study that reports the effectiveness and safety of GLP-IRA in KT patients. Our results support that it can be an option for the management of DM in these patients. Its use is safe and it does not seem to alter tacrolimus trough levels, to induce AR episodes or de novo DSAs development.

Background and Aims: Optimal initial tacrolimus dosing and early exposure of tacrolimus after renal transplantation is not well studied. Based on the assumption that current treatment protocols using frequent trough level determinations in the first week after transplantation may cause overexposure related nephrotoxic side effects and frequent monitoring is costly and not supported by basic pharmacokinetic principles, we had the hypothesis that early low and fixed tacrolimus dosing may be a safe and practical alternative.

Method: In this open-label, multicenter, randomized controlled, non-inferiority study, we randomly assigned 432 renal allograft recipients to receive basiliximab induction, mycophenolate and steroids and either standard prolonged-release tacrolimus (trough levels: 7-9 ng/ml; arm A), or an initial 7-day fixed 5 mg/day dose of prolonged-release tacrolimus followed by lower tacrolimus predose levels (trough levels: 5-7 ng/ml; arm B, see Figure 1). The primary end point was the combined incidence rate of biopsy-proven acute rejections (BPAR; including borderline), graft failure or death at 6 months with a non-inferiority margin of 12.5 %.

Results: The combined primary endpoint in arm B was non-inferior compared to the control arm A (22.1 % versus 20.2 %; difference 95 % CI: 1.9- 8.8 %). While overall rate of BPAR including borderlines were similar (B: 17.4 % vs. A: 16.1 % (see Figure 2), a statistically significant difference of higher than borderline graded BPAR was noted (B: 11.6 % vs. A: 5.2 %; p = 0.027). Safety parameters such as delayed graft function, kidney function, infections or post-transplantation diabetes mellitus did not differ.

Conclusion: An initial fixed low prolonged release tacrolimus dose of 5 mg/day followed by lower tacrolimus exposure is non-inferior compared to standard tacrolimus therapy and equally efficient and safe within 6 months after renal transplantation. (EudraCT-Nr: 2013-001770-19).

Figure 1: Study design.

Depicted is the study design over time. Treatment arm A allograft recipients received basiliximab induction, standard prolonged-release low dose tacrolimus (Low dose Tac), mycophenolate (MMF) and steroids. Treatment arm B allograft recipients received basiliximab induction, initial 7-day fixed 5 mg/day dose of prolonged-release tacrolimus followed by lower tacrolimus predose levels (S&L dose Tac), mycophenolate (MMF) and steroids.
Figure 2: Kaplan Meier Plot of Primary Endpoint & Graft Survival. Shown are a Kaplan-Meier plots for the primary endpoint in panel a) and for graft survival in panel b). Recipients of allografts in treatment arm A received basiliximab induction, standard prolonged-release low dose tacrolimus (low-dose Tac with target trough levels of 7–9 ng/ml), mycophenolate (MMF), and steroids. Allograft recipients in treatment arm B received basiliximab, an initial 7-day fixed dose of 5 mg/day of prolonged-release tacrolimus followed by lower tacrolimus predose levels (S&D dose Tac, with target trough levels of 5–7 ng/ml), mycophenolate (MMF), and steroids. BPAR = biopsy-proven acute rejection.

CELLULAR IMMUNITY ACTIVATION IN RENAL TRANSPLANT RECIPIENTS AFTER VACCINATION WITH TOZINAMERAN: DIFFERENCES BETWEEN RESPONDERS AND NON-RESPONDERS

Stamatia Stai1, Asimina Fylaktou2, Efstratios Kasimatis3, Aliki Xochelli2, Vasiliki Nikolaidou2, Georgios Tsoulfas3, Aikaterini Papagianni4 and Maria Stangou1

1School of Medicine, Aristotle University of Thessaloniki, ‘Hippokration’ General Hospital, Department of Nephrology, Thessaloniki, Greece, 2“Hippokration” General Hospital, National Peripheral Histocompatibility Center - Immunology Department, Thessaloniki, Greece, 3School of Medicine, Aristotle University of Thessaloniki, ‘Hippokration’ General Hospital, Department of Transplant Surgery, Thessaloniki, Greece and 4School of Medicine, Aristotle University of Thessaloniki, ‘Hippokration’ General Hospital, Department of Nephrology, Θεσσαλονίκη, Greece

**Background and Aims:** Response to vaccination is a complex procedure, resulting from the activation of various immune cell subpopulations and comprising stimulation of several interactive pathways. The aim of our study was to assess the differences in cellular subpopulations between Renal Transplant Recipients (RTRs) classified as “responders” and “non-responders” to vaccination with Tozinamern, against severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).

**Method:** Our research was a prospective observational study. Our sample consisted of 39 RTRs on stable immunosuppression, who had a negative history of coronavirus disease 2019 (COVID-19) infection and had not achieved to develop protective humoral immunity (i.e., had a negative test for neutralizing antibodies - Nab-) three weeks after the 2nd vaccine dose (T0). We attempted to evaluate immune response 48 hours before (T1) and 3 weeks after (T2) the 3rd Tozinamern dose. Patients with serum Nab levels > 0.3AU/ml (calculated with chemiluminescence immunoassay -CLIA-) and/or enzyme-linked immunosorbent spot (ELISpot) values > 30SFC/5 × 10^5 PBMCs were regarded as responders. Results were subsequently correlated with variations in cellular subpopulation compositions. Concentrations of CD4+, activated CD4+, CD8+, activated CD8+ T-cells, CD3+CD16+CD56+ (Natural Killer T -NKT-), activated NKT cells, CD3-CD16+CD56+ (Natural Killer -NK-) cells, CD19+, CD19+CD27- (Naïve), CD19+IgD+CD27- (Marginal), CD19+CD24+CD38high (Transitional), CD19+CD27+CD38high (Plasmablasts) and CD19+CD27+ (Memory) B cells were measured with flow cytometry at T1 and T2. We compared the results in the “responders” and the “non-responders” group.

**Results:** The number of responders significantly increased from T1 [17/39, responders: Nab(-) - ELISpot(-)] to T2 [34/39, responders: Nab and/or ELISpot (+)] (x^2 = 16.2, p < 0.0001). No difference was observed between responders and non-responders regarding age, renal function, calcineurin inhibitor levels, dialysis and transplantation vintage. Compared to non-responders, responders presented increased concentrations of: activated CD8+ [23.6(29) vs 9.49(10)/μL, p: 0.044], activated NKT [4.77(8) vs 1.73(2)/μL, p: 0.001] and NK cells [198.91(161) vs 104.45(103)/μL, p: 0.024] at T1 and elevated levels of: total B cells [87.63(101) vs 26.86(42)/μL, p: 0.01], marginal [10.03(13) vs 1.12(5.9)/μL, p: 0.045] and memory B-cells [28.31(42) vs 10.57(19)/μL, p: 0.048] at T2 (see table). A significant increase of activated NKT and naïve B-cells from T1 to T2 [310(174) vs 241(200)/μL, p = 0.02 and 56.2(67) vs 1082(834)/μL, p<0.0001, respectively] was evident only in the responders’ group.

**Conclusion:** As anticipated, responders to vaccination against SARS-CoV-2 exhibited a quite different immune cell activation profile compared to non-responders. Besides, the 3rd Tozinamern vaccine dose substantially improved RTRs’ immune response and induced a prominent stimulation of the B lymphocyte compartment.

EFFECT OF KIDNEY TRANSPLANTATION ON CARDIORESPIRATORY FUNCTION ASSESSED WITH CARDIOPULMONARY EXERCISE TESTING: A SYSTEMATIC REVIEW AND META-ANALYSIS

Eva Pella1, Maria Eleni Alexandrou1, Afroditou Boutou2, Marieta Theodorakopoulou1, Erasmia Sampanis1, Konstantina Dipla1, Andreas Zafeiridis3 and Pantelis Sarafidis3

1Aristotle University of Thessaloniki, Department of Nephrology, Thessaloniki, Greece, 2Aristotle University of Thessaloniki, Department of Respiratory Medicine, Hippokration Hospital, Thessaloniki, Greece and 3Aristotle University of Thessaloniki, Department of Sports Science At Serres, Exercise Physiology and Biochemistry Laboratory, Thessaloniki, Greece

**Background and Aims:** Patients with kidney failure often present with reduced functional cardiovascular reserve and exercise intolerance. Kidney transplantation is the optimal treatment for patients with end-stage kidney
disease as it is associated with longer survival and improved quality of life compared to hemodialysis or peritoneal dialysis.

Method: This is a systematic review and meta-analysis of studies using cardiopulmonary-exercise-testing (CPET) to examine the cardiorespiratory fitness of patients with kidney failure before and after kidney transplantation. The primary outcome was differences in pre- and post-transplantation values of peak oxygen uptake (VO2peak). Literature search involved PubMed, Web of Science and Scopus databases, manual search of article references and grey literature. Quality assessment was undertaken with Newcastle-Ottawa-Scale.

Results: From 379 literature records initially retrieved, 6 studies (207 participants) were included in final meta-analysis. A marginal, but not significant, improvement was observed in oxygen consumption during peak exercise compared to pre-transplantation values (standardised mean difference [SMD]: 0.32, 95%CI −0.02; 0.67). Oxygen consumption at anaerobic threshold (VO2AT) was significantly improved after kidney transplantation (weighted MD [WMD]: 3.97; 24.86). In subgroup analysis, consistent results were shown between changes were observed in maximum heart rate (WMD: 10.45 bpm, 95%CI −3.97; 24.86). In subgroup analysis, consistent results were shown between changes in VO2peak was observed when pooling data reported from follow-up assessments undertaken at least 3 months post-transplantation surgery (SMD: 0.17, 95%CI −0.03; 0.38), but not earlier (WMD: −0.03 ml/kg/min, 95%CI −4.28; 4.23).

Conclusion: Several major indices of cardiorespiratory fitness tend to improve after kidney transplantation compared to pre-transplantation values. This finding may represent another modifiable factor contributing to better survival rates of kidney transplant recipients compared to patients undergoing dialysis.

Method: Potential KTRs were screened for eligibility and approached by their consultant nephrologist, and if interested, further study details were explained by a researcher. Those who consented to take part were randomised (1:1) to either a 12-week structured home-based exercise programme (INT, n = 22) or 12-week usual care control (CTR, n = 23). Figure 1 outlines the home-based exercise programme. The a priori thresholds for specific feasibility and acceptability criteria are as follows: recruitment success of 20% of eligible participants (≥2 participants per month), adherence (an average of three exercise sessions per week) and attrition (<30%).

Results: Ninety patients were approached and 45 (50%) recruited across 22 months of recruitment (currently ongoing). Participant characteristics were: 50±14 years (INT 48±13; CTR 52±13), 21 male (INT 8; CTR 13), eGFR 59±19 ml/min/1.73 m2 (INT 62±19; CTR 58±19), 31 White British (WB) and 14 Asian ethnicity (INT 14 WB, 8 Asian; CTR 17 WB, 6 Asian). Two participants withdrew from the intervention group (1 due to COVID-19 infection, 1 due to recurrent urine infections unrelated to the trial) and one from the control group (lost to follow-up; 7.3% attrition). There were no adverse events reported related to the exercise intervention or trial procedures. Intervention participants (n = 16 completed) recorded an average of 4.5±1.4 exercise sessions per week (aerobic 2.9±1.2; strength 1.6±0.4).

Conclusion: Results suggest engagement with the home-based exercise programme in KTRs is excellent. The study is comfortably exceeding a priori thresholds relating to recruitment, retention and completion suggesting patients are interested in the study and the programme of exercise despite the current evidence showing physical activity levels are low. The groups are well matched and there is encouraging representation of female participants and participants from a non-white background. These initial results support study continuation and further assessment and development of home-based programmes of exercise and activity for KTR.

Figure 1: Change in VO2peak values before and after kidney transplantation.

FEASIBILITY OF HOME-BASED EXERCISE IN KIDNEY TRANSPLANT RECIPIENTS: PARTICIPANT CHARACTERISTICS AND INITIAL RESULTS FROM THE ECSERT TRIAL
Roseanne E Billany1, Zahra Mubaarak1, Stephanie Burns2, Hannah Young3, Nicolette Bishop4, Alice Smith3 and Matthew Graham-Brown1,2
1University of Leicester, Department of Cardiovascular Sciences, United Kingdom, 2University Hospitals of Leicester NHS Trust, John Walls Renal Unit, Leicester, United Kingdom, 3University of Leicester, Department of Population Health Sciences, United Kingdom and 4Loughborough University, School of Sport, Exercise and Health Sciences, United Kingdom

Background and Aims: Kidney transplant recipients (KTR) are prone to high rates of infection, malignancy and cardiovascular disease. Poor physical fitness and physical inactivity remain pertinent targets to improve post-transplant clinical outcomes. Only 27% of KTR are classified as physically active for health. The ECSERT pilot randomised controlled trial aims to assess the feasibility of delivering a structured, home-based exercise intervention in 50 KTR at increased cardiometabolic risk and evaluate the putative effects on cardiovascular structure and function, cardiorespiratory fitness, physical function, quality of life, metabolic and inflammatory markers. We present interim feasibility data describing engagement with the home-based programme of exercise for all patients who have completed the programme to date.
EXERCISE AND PREDIABETES AFTER RENAL TRANSPLANTATION: THE EXPRED I STUDY

1University of La Laguna, Faculty of Medicine, San Cristóbal de La Laguna, Spain, 2University hospital of Canary Island, Nephrology, Spain, 3University hospital of Canary Island, Research unit, Spain and 4University of La Laguna, Faculty of Medicine, Spain

Background and Aims: Post-Transplant Diabetes Mellitus (PTDM) is a severe disease that may affect about 30% of renal transplant patients. PTDM beyond 12 months (late PTDM) mostly develops in subjects with prediabetes. Although exercise may have a potential role in preventing late PTDM, there is scarce evidence on the effect of exercise in renal transplantation. We designed a 12-month exploratory study to test the capacity of therapeutic exercise in reverting prediabetes to prevent the development of late-PTDM.

Method: This is a pilot study in which renal transplant patients with prediabetes were treated with exercise for 12 months. To detect prediabetes and to evaluate the reversibility, relapse, or persistence of prediabetes, the oral glucosetolerancetest(OGTT)wasperformedatbaselineandevery3months to the end of the study; Prediabetes was defined by the presence of Impaired Fasting Glucose (IFG) in 100-125 mg/dl and/or Impaired Glucose Tolerance (IGT) between 140-199 mg/dL after the OGTT. The protocol included a stepped incremental plan of aerobic and/or strength training. The frequency, intensity, and duration of aerobic exercise, as well as the addition of strength training depended on the recovery, persistence, or recurrence of prediabetes.

All patients started with moderate aerobic exercise (brisk walking), 30 min/day and 5 times per week and, based on that, changes in prescription were considered every 3 months. Additionally, we evaluated: (a) an active plan for promoting adherence to exercise (telephone calls, digital technology, and visits) and (b) improvements in metabolic risk factors: obesity, dyslipidaemia, and blood pressure. Since prediabetes may spontaneously revert to normal glucose metabolism in 25-30% [1], we assume that in 60 cases, the spontaneous reversibility could be of 30% (n = 18) and the reversibility induced by exercise may account for another 30% (n = 18), so the total reversibility will be 60%. Considering an expected drop out of 20%, the number of cases necessary to include was 72 patients.

Results: The study was early interrupted due to efficacy after the evaluation of 27 patients that reach 12 months of follow-up. Mean age was 54.2 ± 9.6 and 67% were men. Half of the patients were obese and most had overweight. At baseline IGT or IFG alone were found, respectively, in 13 (48%) and 5 (19%) patients, and the combination of both in 9 (33%). All patients were on prednisone and tacrolimus with the addition of mycophenolate on 20 subjects and 7 on everolimus. Of the group, 16 (60%) reverted to normal glucose levels (fasting and 120 min after an OGTT): this was two time higher than the 30% reversibility rate shown in a previous publication [1], p <0.05, assuming a potency of 85%. In parallel, 11 (40%) subjects had prediabetes (9) or developed PTDM (2). No significant changes were found in weight during follow-up in all groups whereas triglycerides diminished in patients on whom prediabetes reverted (154 mg/dL ± 61 to 96 ± 27; p = 0.016). At the end of follow up, adherence to exercise was good (≥70%) in 13 patients (~50%), moderate (40-70%) in 9 (~30%) and bad (<40%) in 5 (~20%). Finally, all patients with good adherence reverted to normoglycaemia, 3 out of 9 (33%) cases with moderate adhered to normal glucose metabolism and no cases with bad adherence improved on follow-up. No relevant injuries attributed to exercise were observed during the study.

Conclusion: Therapeutic exercise is safe and effective to improve glucose metabolism in renal transplant patients with prediabetes. Adherence is a crucial aspect to consider in the planification of exercise treatment.

SAFETY AND EFFICACY OF EVOLOCUMAB AMONG KIDNEY TRANSPLANT PATIENTS AT HIGH CARDIOVASCULAR RISK

Torki Alotaibi1, Ayman Maher Nagib1,2, Hasaneen Hasaneen Ahmed Aboatya Aboatya1, Medhat Abdulhalim1, Tarek Said1, Mohamed Emam1, Zakaria Elsayed3, Prasad Nair2 and Osama Ashry Ahmed Gheith1,2

1OTC Kuwait, Nephrology, Ff, Kuwait and 2Mansoura university, Nephrology, Mansoura, Egypt

Background and Aims: Proprotein convertase subtilisin/Kexin type A (PCSK-9) inhibitors have not been evaluated among kidney transplant recipients (KTR) despite its favorable cardiovascular profile. We aimed to evaluate the safety and efficacy of evolocumab in reducing lipids and cardiovascular events among risky KTR.

Method: One hundred ninety-five KTR - who were followed up in Hamed Al-Essa organ transplant center with high cardiovascular risk score (>20)- were enrolled in this prospective randomized controlled study between June 2017 and June 2018. Patients who received statin and evolocumab (140 mg/ 2 weeks, group1, n = 97) while those maintained on statin alone comprised group 2(n = 98). After 24 months, they were followed up clinically and by laboratory investigations.

Results: The two groups had comparable demographics. Before enrollment in the study, we observed a higher prevalence of NODAT in group 2 and...
Relativereceptor binding domain (RBD) fading over time in different patient groups and dependent on vaccine type. Each thin line corresponds the anti-Spike S1 protein RBD antibody values (Euroimmun) of a study participant from T2 (eight weeks after vaccination start) via T3 (six months after vaccination start) to T4 (nine months after vaccination). The thicker lines represent median responses by vaccine type (green-BNT162b2mRNA and red 1273-mRNA) in each group. Only patients with successful de novo seroconversion at T2 (IgA or IgG antibody positivity against the SARS-CoV-2 S1 protein) after 2x mRNA vaccination and without SARS-CoV-2 nucleocapsid (NCP) antibodies were considered. Reference range of the test used, < 20 = negative, ≥ 20 - < 35 = grey range (the latter two categories synonymous with below positivity level), ≥ 35 = positive test result. The vertical axis is depicted on log_{10} scale with corresponding unit % inhibition. MP = Medical Personnel, DP = Dialysis Patients, KTR = Kidney Transplant Recipients, AP = Lipidapheresis Patient.

The table summarizes the average group rates of antibody decline that were estimated using a hierarchical linear mixed-effects model with the natural logarithm of raw RBD-antibody values as response, fixed effects for group, time, and their interaction, random intercept (per subject) and random slope (over time). The 95% confidence intervals were obtained from posthoc pairwise analysis.

participants including healthy MP (125), DP (595), KTR (111), and apheresis patients (49-AP) with positive seroconversion (de novo IgA or IgG antibody positivity by ELISA) after eight weeks.

**Results:** Nine months after first vaccination, receptor binding domain (RBD) antibodies were still positive in 90 % of MP, 86 % of AP, but only 55 %/48 % of DP/KTR, respectively. Seroconversion remained positive in 100 % of AP and 99·2 % of MP, but 86 %/81 % of DP/KTR, respectively. Compared to MP, DP but not KTR or AP were at risk for a strong RBD decline, while KTR kept lowest RBD values over time (see Fig. 1 and Table 1). By multivariate analysis, BNT162b2mRNA versus 1273-mRNA vaccine type was an independent risk factor for a strong decline of RBD antibodies. Within the DP group, only time on dialysis was another (inverse) risk factor for the DP group. Compared to humoral immunity, T-cell immunity decline was less prominent.

**Conclusion:** While seroconverted KTR reach lowest RBD values over time, DP are at specific risk for a strong decline of RBD antibodies after successful SARS-CoV-2mRNA vaccination, which also depends on the vaccine type being used. Therefore, booster vaccinations for DP should be considered earlier compared to normal population.

**Result:** Risk of strong antibody decline in dialysis or renal transplant patients compared to general population. We hypothesized that COVID-19 preexposure influences not only vaccination dependent development of immunity but also protects from immunity fading depending on vaccine type and patient group.

**Method:** We evaluated two and nine months follow up data in our observational DIA-Vacc study exploring specific cellular (interferon-γ release assay = IGRA) or/and humoral immune responses after 2x SARS-CoV-2mRNA vaccination in 2615 participants including medical personnel (300 MP), dialysis patients (1831 DP), kidney transplant recipients (484 KTR). Study participants were separated into COVID-19 preexposure positive (n = 405) versus negative (n = 2210) groups, where symptomatic or asymptomatic COVID-19 disease before start of vaccination was confirmed by clinical symptoms, PCR positivity and/or Spike S1/core antiSARS-CoV-2 antibodies.

**Results:** Two months (T2) after first vaccination, seroconversion and T-cell immunity success rates for MP and DP were excellent (86-100%) and independent on COVID-preexposure. In KTR, vaccination-related seroconversion rate on T2 almost doubled with COVID-preexposure (84% versus 45% without), a result consistent with all different antibody measurements (IgA, IgG, or receptor binding domain-RBD). Nine months after first vaccination in COVID-19 negative study patients, the percentage of patients with RBD-antibody fading results >50% remained low in MP (18%), high in DP (53%) and intermediate in KTR (39%). In contrast, in all patient groups with COVID-19 preexposure RBD-antibody fading reactions >50% within nine months after vaccination were almost vanished (4% in MP, 8% in DP and 0% in KTR). COVID-19 preexposure in DP also reduced T-cell immunity fading as measured by IGRA, where only 9% of patients showed a >50% titer decrease compared to 34% of DP without any COVID-19 preexposure. Similar results were also seen regarding vaccination dependent regulation of antiSARS-CoV-2 IgG antibodies dependent on COVID-19 preexposure. These results are also reflected by increased mean antibody titers for IgG- and RBD-antibodies nine months after vaccination in all COVID-19 preexposed compared to non-exposed groups. In addition, the degree of antibody fading after vaccination was not just dependent on COVID-19 preexposure status but also on mRNA vaccine type being used. In MP with COVID-preexposure, 22% of BNT162b2mRNA but 0% of 1273-mRNA vaccinated study participants experienced RBD-antibody fading >50% within nine months after vaccination start. This significant difference was even greater in COVID-19 preexposed DP, in whom vaccination with BNT162b2mRNA caused RBD-antibody fading >50% in 3% compared to 6% of 1273-mRNA treated DP. The patient number in the KTR group was not high enough for a vaccine type comparison. This vaccine dependent influence of antibody fading is consistent with our results in patient groups without COVID-19 preexposure.

**Conclusion:** Long term immunity time course is markedly modified via COVID-preexposure in a mRNA vaccine dependent manner. Hybrid immunity after COVID-19 preexposure almost completely lacks immunity fading between two and nine months especially in 1273-mRNA vaccinated MP, DP, or KTR. Immune monitoring shows great individual variability dependent on personal patient history and should be especially used for pandemic patient management in vulnerable groups such as DP and KTR.
#5841
UTILITY AND ACCEPTANCE OF TELENEPHROLOGY AMONG KIDNEY TRANSPLANT RECIPIENTS IN A PUBLIC SECTOR HOSPITAL IN A DEVELOPING COUNTRY
Arunkumar Subbiah, Kristin George, Raj Kanwar Yadav, Soumita Bagchi, Sandeep Mahajan, Dipankar Bhowmik and Sanjay Kumar Agarwal
All India Institute of Medical Sciences (AIIMS), Nephrology, New Delhi, India

Background and Aims: The importance of telemedicine in delivering renal health care has come to light during the COVID-19 pandemic. Moreover, specialist care to transplant recipients is often limited to urban areas especially in developing countries. Telenephrology offsets this discrepancy enabling quality care to patients in rural areas. But, apart from availability, the true success and future of telenephrology depends primarily on patients’ acceptance. This study was performed to assess the feasibility, patient attitude and acceptance of telenephrology services among renal transplant recipients at our institute, a public sector hospital in a developing country.

Methods: This single-centre cross-sectional study included renal transplant recipients who availed our telenephrology services for at least 3 months. A total of 100 transplant recipients were selected by stratified random sampling from the list of attendees of telenephrology consultation and included in this study.

The study questionnaire was administered in local language by the telephone interview method.

Results: The mean age of our study cohort was 32.83 ± 9.96 years (16–55yrs) and 92% were males. The median number of teleconsultations availed by the patients was 3 (1–20). The questionnaire was answered by the patient himself/herself in 89% cases, spouse in 7% and children in 3% cases.

Only thirty-nine (39%) patients were graduates or post graduates. Over one-half (51%) of the patients belonged to the lower-middle socioeconomic class as per the modified Kuppuswamy classification. Prior to initiation of the telenephrology service, the median distance travelled to attend our outpatient department (OPD) was 304.5 Km (6 – 1673 km). Most (87%) of our patients used public transport to attend OPD. Three-fourths (79%) of the patients were accompanied by family members for their OPD visit. Attendees incurred productivity loss due to missed work days in 57% of the cases. The median cost of each OPD visit was 3000 (40-15000) INR. Almost all the transplant recipients felt that Telenephrology service was a right approach during the COVID-19 pandemic. 98% of the patients said that they were confident discussing their complaints over phone while 99% of our patients were comfortable sharing reports over phone. Majority (>90%) of the patients gave a satisfaction score of 4 (out of 5) for their telenephrology experience.

The most important benefit (79%) of telenephrology as perceived by the transplant recipients was financial benefit of avoiding travel and workdays saved. Regarding the problems faced during teleconsultation, 22% patients responded that they wish to see the doctor in person to feel satisfied; 5% had problems with availability of investigations locally. Only a small fraction (2%) of patients had difficulty in explaining symptoms over a tele-consult. A significant (97%) patients felt that Telenephrology services should continue in combination with physical OPD services.

Conclusion: Telenephrology is feasible and acceptable to kidney transplant recipients irrespective of literacy status across all socio-economic classes. In developing countries like India, telenephrology has immense potential to provide quality nephrology care.

#3185
INFLUENCE OF COMBINED CYP 3A4/5 AND POR*28 GENETIC POLYMORPHISMS ON TACROLIMUS AND CYCLOSPORINE DOSE REQUIREMENTS IN INCIDENT RENAL TRANSPLANT PATIENTS
Magdy Elsharkawy1,2, Dina Isma1,2, Abdel-Hameed Ebid3, Neama Lotfy2 and Mohamed Mahmoud5
1Ain Shams University, Nephrology, Cairo, Egypt, 2Ain Shams University, Pharmacy, Cairo, Egypt and 3Helwan University, Pharmacy, Cairo, Egypt

Background and Aims: Calcineurin inhibitors, cyclosporine and tacrolimus have a narrow therapeutic index and have wide intra- and inter individual pharmacokinetic variability. They are metabolized mainly by CYP3A4 and CYP3A5. The P450 oxidoreductase POR*28 variant allele has been associated with changes in cytochrome P450 enzymatic activity that can affect the therapeutic level of both medications. The aim of this study is to investigate the allelic frequency of the POR*28 in Egyptian renal transplant patients and to evaluate the effect of the presence of CYP3A4*3/CYP3A5*1 genotypes on calcineurin inhibitos dose requirements and adjustments.

Method: A prospective clinical trial that included 130 renal transplant patients placed on either tacrolimus or cyclosporine. Patients were genotyped for either of the following POR*28 genotypes CYP3A4*22, CYP3A4*22 and CYP3A4*22, CYP3A5*1.

Figure: POR*28, CYP3A4*22, and CYP3A5*1. The relation between the present genetic polymorphisms and tacrolimus and cyclosporine doses and dose adjustments were studied at days 14, 30, and 90 post-transplantation.

Results: The POR*28 allele frequency in the studied population was 29.61%. The tacrolimus dose-adjusted trough concentration ratio (C0/D) was highly statistically significant in the fast metabolizers group (CYP3A4*1/POR*28 carriers) than in the slow metabolizers group (CYP3A4*3/*3/CYP3A5*22 carriers) throughout the study (14, 30, and 90 days) (p value 0.001, <0.001, and 0.003, respectively). There was no significant effect for this gene combination on cyclosporine (C0/D).

Conclusion: Combining the CYP3A4*1, POR*28, and CYP3A4*22 genotypes can be of significant value in early tacrolimus dose requirements and adjustments. However, it does not have any influence on cyclosporine dose requirements.

A FEASIBILITY STUDY EXPLORING THE IMPACT OF A LOW ADVANCED GLYCAZATION END-PRODUCT DIET ON SKIN AUTOFLUORESCENCE IN KIDNEY TRANSPLANT RECIPIENTS
Daniela Viramontes Hörner1, Maarten Taal1,2, Janson Leung3, Ellen Patullo4 and Catherine Johnson2
1Centre for Kidney Research and Innovation, Academic Unit for Translational Medical Sciences, School of Medicine, University of Nottingham, Derby, United Kingdom and 2Department of Renal Medicine, University Hospitals of Derby and Burton NHS Foundation Trust, Derby, United Kingdom

Background and Aims: Advanced glycation end-products (AGEs) are uremic toxins that result from hyperglycaemia and oxidative stress. AGEs are also formed in food, especially during cooking using dry-heat methods. AGE accumulation can be measured by skin autofluorescence (SAF) and increased SAF is a strong predictor of death and graft loss in kidney transplant recipients (KTR). Previous studies have reported that reduction of dietary AGE intake is associated with a decrease in circulating AGE levels, suggesting that a low-AGE diet may slow the progression of atherosclerotic disease in KTR.

Methods: Ten KTR were included in this feasibility study and were randomly assigned to a low-AGE diet (LAE) or a usual-care diet (UC). A high-AGE diet was used as a comparator. Dietary AGE intake was assessed using dietary AGE questionnaires and food frequency questionnaires. A validated AGE food database was used to estimate AGE intake. AFP, NGAL, SAF, and urinary AGEs were assessed at baseline and at 3 months.

Results: Participants in the LAE group had a decrease in AGE intake of 91% compared to the UC group. A decrease in circulating AGE levels was reported in both groups, with a significantly greater decrease in the LAE group. SAF was significantly reduced in the LAE group compared to the UC group. No significant changes in urinary AGE levels were observed.

Conclusion: A low-AGE diet is feasible in KTR and leads to reduced AGE intake and improved skin autofluorescence.
Table 1: Changes in skin autofluorescence, dietary AGE intake and nutritional markers from baseline to 6 months in intervention and control groups.

diet may also be associated with a decrease in SAF. The aim of this feasibility study was to investigate whether a low-AGE diet leads to a reduction in SAF levels in KTR.

Methods: Thirty-eight KTR were randomly allocated to a usual diet (control group, n = 19) or a low-AGE diet (intervention group, n = 19) and then followed-up for 6 months. The intervention group was provided with detailed written advice and counselling on how to choose foods low in AGES, and to use high-water content cooking methods (stewing, steaming, boiling, poaching), instead of dry-heat methods (frying, grilling, roasting). The goal was to reduce dietary AGE intake to < 8000 kilounits/day (kU/day). SAF was measured at baseline, 3 and 6 months. Rate of change in SAF (i.e., SAF trend) was calculated using the SLOPE function in Microsoft Excel. Dietary AGE intake, biochemistry and nutritional assessments were performed at baseline and 6 months.

Results: Mean age of the whole cohort was 56±11 years. Mean SAF was high at 2.9±0.7 arbitrary units (AU) compared to the reference value of 2.1±0.4 AU. Transplant vintage ranged from 42 to 126 (median 88) months. The majority of the participants were male (71%) and of white ethnicity (84%). Prevalence of diabetes, hypertension and heart disease was 16%, 53%, and 10%, respectively. Median dietary AGE intake was high at 18558 (15164 to 25341) kU/day. SAF was measured at baseline, 3 and 6 months. Rate of change in SAF (i.e., SAF trend) was calculated using the SLOPE function in Microsoft Excel. Dietary AGE intake, biochemistry and nutritional assessments were performed at baseline and 6 months.

P-values in columns are for comparison of baseline and 6-month data within each group.

significant in the intervention group but remained high in the control group. Body weight, energy, and fat intake decreased in the intervention group but there was no significant change in SAF (Table 1). The mean SAF trend observed was a decrease of 0.45±1.19 and 0.22±0.75 AU/year in the intervention and control groups, respectively (p = 0.7 for comparison between groups).

Conclusion: In this feasibility study, we observed a high drop-out rate in the intervention group, which may explain our finding that reduction in dietary AGE intake did not seem to have any significant effect in decreasing SAF levels. This highlights the need for a larger trial to determine the effect of dietary AGE restriction on SAF levels in KTR.

#3895 COMPARABLE RENO-CARDIAC PROTECTIVE EFFECTS OF SGLT2 INHIBITION VERSUS DPP-4 INHIBITION IN DIABETIC KIDNEY TRANSPLANT RECIPIENTS: KUWAIT EXPERIENCE

Torki Alotaibi¹, Osama Ashry Ahmed Gheith²,³, Zakaria Elsayed²,³, Ahmed Tahya³, Mahmoud Shaker³, Mahmoud Khalid³, Mohamed Enam³, Muhammad Hammad³, Ayman Maher Nagib²,³, Mohamed Mostafa³, Ahmed Denewar²,³, Mohamed Ahmed Abdulkhalek Zahab²,³, Prasad Nair³, Nashwa Elserwy³ and Nabil Elserwy³

¹Hamed Alessa organ transplant center, kuwait, Nephrology, Kuwait, kuwait, Nephrology, Mansoura, Egypt

Abstracts i941
Background and Aims: Diabetes is the most common cause of chronic kidney disease (CKD) globally. The renal and cardiovascular benefits of the new anti-diabetic agents are not assessed comprehensively. We aimed to evaluate the short term renal and cardio-protective effects of Sodium-Glucose Cotransporter-2 Inhibition (SGLT2i) Vs. Dipeptidyl peptidase-4 Inhibition (DPP4i) among diabetic kidney transplant recipients.

Method: In this observational trial, 222 diabetic kidney transplant recipients (NODAT or type 2 diabetes) were enrolled and were categorized into two groups. Group 1 (n = 99) received SGLT2i while group 2 (n = 123) received DPP4i as an add on anti-diabetic medications. All patients in the two groups were followed up for 12 months.

Results: Most patients in the two groups (182) were men (59.6 vs. 61.7%, p = 0.73) in their middle age (58.3±11.9 vs. 54.4±12.9, p = 0.016) years respectively. The two groups were matched regarding their demographics especially the type of donor, type of immunosuppression (induction or maintenance), number of cardiovascular events before enrollment in the study and the number of patients who were maintained on ACEi or ARB(p>0.05). The minority of patients were smokers (12.9 vs.8.7%), and chronic glomerulonephritis was the original disease in 36.4 vs. 35.4% in the two groups, respectively. Most of the enrolled patients (72.8 vs. 76.8%) underwent hemodialysis pre-transplant. During follow up period, patients in both groups were comparable regarding mean blood pressure, body weight, HbA1C, 24-hour urine protein, and graft function (represented by the mean serum creatinine at different time intervals and compared to base line values(p>0.05). However, the mean HbA1C was significantly higher in group 1 during the whole follow up period of the study (p<0.05) but it did not drop significantly compared to baseline values (p>0.05). We did not report any macroangiopathic events (cerebral stroke, acute myocardial infection, or peripheral arterial disease) in the two groups during the study.

Conclusion: Both GLT2i and DPP-4 I are comparable regarding renal and cardio-vascular protection among diabetic kidney transplant recipients.

CARDIORESPIRATORY FITNESS IN KIDNEY TRANSPLANT RECIPIENTS: A CASE-CONTROL STUDY AND INITIAL REVIEW OF THE EFFECTS OF A HOME-BASED EXERCISE PROGRAMME

Rozanne E Billany1, Zahra Mubarak2, Stephanie Burns2, Noemi Vadaszy2, Nicolette Bishop2, Alice Smith3, Gerry McCann4, and Matthew Graham-Brown2,1

1University of Leicester, Department of Cardiovascular Sciences, Leicester, United Kingdom, 2University Hospitals of Leicester NHS Trust, John Walls Renal Unit, United Kingdom, 3University of Leicester, Department of Population Health Sciences, United Kingdom and 4Loughborough University, School of Sport, Exercise and Health Sciences, United Kingdom

Background and Aims: Kidney transplant recipients (KTRs) have an increased burden of cardiovascular disease (CVD) due to clustering of traditional and non-traditional risk factors. Poor cardiorespiratory fitness (CRF) is linked to higher levels of morbidity and mortality. Cardiorespiratory fitness is a significant predictor of 7-year risk of mortality, with each 1 ml/kg/min increase in VO2 associated with a 1% decrease in risk of mortality.[1] Although KTRs have higher CRF than patients with kidney failure, performance compared to the general population has not been quantified. Neither has the link between CRF and physical function. We assessed differences in CRF between KTRs and healthy volunteers in a case-control study. We then explored relationships between CRF and physical function and possible effects of a 12-week structured home-based exercise programme in KTRs.

Method: Case-control: 20 KTRs (10 male; age 61.2 ±8.1 years; body mass 84.1 ±19.9 kg) and 20 healthy volunteers (10 male; age 61.9 ±7.7 years; body mass 76.7 ±18.1 kg) completed a continuous ramp cardiopulmonary exercise test (CPET) to volitional exhaustion on a cycle ergometer. CPET variables were compared between groups using independent samples t-tests. Thirteen KTRs (6 male; age 47.8 ±15.9 years; eGFR 64.6 ±19.1/ml/min/1.73 m2), to date, have completed a 12-week structured, combined aerobic and resistance, home-based exercise programme as part of a pilot randomised controlled trial.[2] Bivariate correlations were used to explore the association between cardiorespiratory fitness and physical function measures (sit-to-stand 60 [STS60], timed up and go [TUG], gait speed [GS] and handgrip strength [HGS]). Paired samples t-tests were used to compare pre- and post-intervention variables.

Results: Case-control: Cardiorespiratory fitness (VO2 peak) was lower in KTRs (18.4±5.2 ml/kg/min) than in healthy volunteers (24.3 ±5.9 ml/kg/min), a difference of 5.9 ml/kg/min (95% CI, 2.4-9.5), t(38) = 3.35, p <.001. Peak heart rate achieved was higher in healthy volunteers than in KTRs (154 v 136 bpm; p = .009). Maximum power achieved was higher in healthy volunteers but did not reach significance (147 v 116 W; p = .052). There was a positive correlation between STS60 and VO2 peak (r = .652, p = .016) and between GS and VO2 peak (r = .583, p = .037). There was a negative correlation between TUG and VO2 peak (r = -.664, p = .013) and no association between HGS and VO2 peak. There was an increase in VO2 peak after the 12-week exercise programme (19.4±4.5 ml/kg/min to 20.4±4.5 ml/kg/min, p = .018). Maximum power achieved did not change post-intervention (118 v 121 W; p = .423). STS60 was the only physical function test to improve post-intervention (24 v 27; p = .010).

Conclusion: Cardiorespiratory fitness in KTRs is significantly impaired compared to healthy control subjects. In KTRs, aerobic fitness assessed with VO2 peak correlated with field tests assessing physical function. Initial findings suggest that CRF may improve following a structured, home-based programme of exercise, but these data need confirming in larger studies and will be assessed in the final analysis of this pilot randomised trial.

LOW DOSE THYMoglobulin-BASILIXIMAB INDUCTION PROTOCOL ON INCIDENCE OF ACUTE REJECTION AND POSTTRANSPLANT NEOPLASIA: AN OBSERVATIONAL RETROSPECTIVE STUDY

Andrea Dello Strologo, Giulia Bartoli, Elisabetta Schifano, Maria Arena, Maria Paola Salerno, Patrizia Silvestri, Franco Citterio, Jacopo Romagno1 and Giuseppe Grandaliano1

1 Dipartimento di Medicina e Chirurgia Traslazionale, Università Cattolica del Sacro Cuore, Nephrology, Neapol, Italy and 2 Dipartimento di Medicina e Chirurgia Traslazionale, Università Cattolica del Sacro Cuore, Kidney Transplant surgery Unit, Rome, Italy

Background and Aims: Induction therapy plays a key role in the prevention of 1-year acute rejection in kidney transplantation. Several studies suggest that depleting drugs, including thymoglobulin (ATG), are superior to anti-CD25 antibodies in reducing the incidence of acute rejection. However, large retrospective investigations demonstrate a close and significant association between the use of depleting agents and the development of post-transplant neoplasia, in particular post-transplant lymphoproliferative disease. Thus, in the attempt to improve the risk/benefit profile of antibody therapy, we implemented an induction protocol based on low-dose ATG and anti-CD25 blocker basiliximab (Bas). The aim of the present study was to evaluate the efficacy and safety of this approach compared to standard dose ATG alone and basiliximab alone.

Method: This is an observational, retrospective, single center study including 957 patients receiving a single kidney transplant the Gemelli kidney transplant center from January 2000 to February 2022. The primary efficacy outcome was biopsy proven acute rejection and the primary safety outcome was the development of post-transplant neoplasia. Patients in the ATG group received a cumulative dose of 7mg/kg in the first week after transplantation; patients in the Bas group were administered the anti-CD25 antibody at a dose of 20 mg before surgery and 20 mg 4 days after transplantation. Finally, patients in the ATG-Bas group received ATG at a cumulative concentration of 3mg/kg over the first 6 days after transplantation and Bas at a dose of 20 mg before surgery and 20 mg 4 days after transplantation.

Results: In our study population we evaluated 154 patients in the standard ATG group, 492 patients in the low ATG-Bas group and 311 patients in the Bas group. No statistical difference for age, mismatches, donor type and donor age, pre-transplant PRA was observed among groups. Use of mTOR inhibitors was more frequent in the standard ATG and low ATG-Bas groups compared to Bas group (80/154, 155/492, 76/311, respectively; p<0.001). We did not observe any significant difference in the use of other maintenance immunosuppressive drugs. Multivariate analysis (Cox model, including number of mismatches, presence of DSA at transplantation and use of mTOR inhibitors) demonstrated that only low ATG-Bas treatment (HR 0.509 95%CI 0.344-0.754, p<0.001), but not standard ATG (HR 0.819 95%CI 0.472-1.423, p=0.5, was able to reduce the risk for acute rejection compared to Bas alone. On the other hand, multivariate analysis (Cox model including acute rejection, age, use of mTOR inhibitors) demonstrated that standard ATG induction (HR 1.677 95%CI 1.035-2.717, p=0.03), but not low ATG-Bas (HR 1.324 95%CI 0.930-1.884, p=0.1), significantly increased the risk for the development of post-transplant neoplasia compared to Bas alone.

Conclusion: In this retrospective analysis we demonstrated that low ATG-Bas protocol was the most effective treatment in preventing biopsy-proven acute rejection. In addition, on the contrary of standard ATG dose protocol it did not increase the risk of post-transplant neoplasia compared to Bas alone induction therapy.

ISLET TRANSPLANTATION VERSUS INSULIN ALONE IN TYPE 1 DIABETIC KIDNEY TRANSPLANT Recipients: A FRENCH NATIONWIDE STUDY ON BEHALF OF THE TREPID GROUP

Mehdi Maanaoui1,2, Rémi Lenain, Yohann Foucher, Mikael Chetboun1, Julie Kerr-Conde1, Gilles Blanchon1, Fanny Buron1, Sandrine Lablanche1, Sophie Caillard1, Laurence Kessler1, Thierry Berney1, Marie-Christine Vantyghem1,2,3, Marc Hazan1 and Francois Pattou1,2

1 CHU Lille, Nephrology, France, 2 INSERM, U1910, Lille, France, 3 CHU Lille, Nephrology, Lille, France, 4 CHU Poitiers, Plateforme de Méthodologie, Poitiers, France, 5 CHU Lille, Endocrine Surgery, Lille, France, 6 CHU Nantes, Nephrology, Nantes, France, 7 CHU Lyon, Nephrology, Lyon, France, 8 CHU Grenoble, Endocrinology, Grenoble, France, 9 CHU Strasbourg, Nephrology, Strasbourg, France, 10 CHU Strasbourg, Endocrinology, Strasbourg, France

Background and Aims: Islet transplantation is associated with a benefit on glycemic control compared to optimized insulin therapy in recent clinical trials. However, there is a lack of evidence concerning the long-term impact of islet transplantation on type 1 diabetic kidney transplant recipients’ prognosis.

Method: Every type 1 diabetic recipient transplanted with a kidney in France between 2000 and 2017 was included. Patients transplanted with pancreatic islets were compared to controls treated with insulin alone according to a matching method based on time-dependent propensity scores (using the following variables: yera of transplantation, donor age, and recipient age, serum creatinine, HBA1c, BMI, cardiovascular background) which allow to ensure patients comparability at the time of islet transplantation. The primary outcome was graft failure, defined by death or return to dialysis.

Results: Among 2393 type 1 diabetic patients transplanted with a kidney during the study period, 381 were eligible to islet transplantation, including 47 that were actually transplanted with islets. Median time for islet transplantation was 34.8 months [21.8–48.4]. Probabilities of insulino-independence and islet graft survival at 1, 5 and 10 years were respectively 63.8% [51.5-79.2], 46.3% [33.9-63.2], 38.7% [25.9-57.8] and 89.4% [81.0-98.6], 87.2% [78.2-97.3], 78.2% [66.2-92.4]. After matching, we observed a significant benefit of islet transplantation compared to insulin alone on graft failure, with a HR of 0.48 [0.20-0.94], mainly explained by a protective effect on the risk of death (HR = 0.38 [0.11-0.95]). We finally estimated the life-expectancy for a 10-year follow-up and found 9.61 years [9.02-10.00] in the islet transplantation group versus 8.85 years [7.97-9.56], with a difference of 8.88 months [-2.16-20.44]

Conclusion: We observe a significant benefit of islet transplantation on the risk of graft failure and death in type 1 diabetic kidney transplant recipients. These results provide incentives to promote islet transplantation in this population.
#3754
GLUCAGON-LIKE PEPTIDE TYPE 1 (aGLP1) AGONISTS AND THEIR INITIATION IN KIDNEY TRANSPLANTATION
Rómulo Katsu Loayza López, Nancy Daniela Valencia Morales, María Muñiz Rincón, Aarón Aíñíl Meneses, Beatriz Rodríguez Cubillío, María Ángeles Moreno de la Higuera Díaz, Natividad Calvo Romero, Isabel Pérez-Flores and Ana Sanchez Fructuoso
Hospital Universitario Clinico San Carlos, Nephrology, Madrid, Spain

Background and Aims: Glucagon-like peptide type 1 agonists (aGLP1) is an important therapy to consider for patients with type 2 diabetes (DM2), especially those with chronic disease with glomerular filtration rates (GFR) up to 15ml/min. They stimulate the production and secretion of insulin from pancreatic β cells, delay gastric emptying, promote weight loss, reduce appetite by acting on the central nervous system, and decrease glucagon secretion from pancreatic α cells.

OUTCOMES: To assess the serum, urinary and clinical effects of treatment with aGLP1 in kidney transplant (KT) patients.

Method: This is a retrospective observational study of 32 KT patients from our center who met criteria for treatment with aGLP1. In the sample, serum and urinary data are compared, six months before, after and at the time of intervention. The management of DM was evaluated with glycosylated hemoglobin (HbA1C) and basal glycemia levels, before and after the start of treatment. Changes in cardiovascular risk are studied with the number of heart failure episodes, hospital admissions, and changes in the left ventricular ejection fraction. In addition, other parameters such as: hemoglobin (Hb), iron, ferritin, calcium, phosphorus, magnesium, potassium, uric acid, proteinuria and clinical data such as body weight were assessed.

Results: The sample presented a mean GFR by CKD EPI of 43.2ml/min. A significant drop in body weight was observed, from 93.3kg to 89.2kg (p = 0.001). Regarding the control of DM, no statistically significant results were obtained, a decrease in glycemia figures from 136 to 133 g/dl and HbA1C was obtained, with a reduction of 2.7%, p = 0.404 and p = 0.105, respectively. Regarding the progression of kidney disease, a decrease in proteinuria from 0.33g/day to 0.25 g/day was obtained, as well as a 9.5% protein/creatinine ratio, p = 0.480 and p = 0.721, respectively. Serum creatinine levels unchanged, with a mean of 1.6 mg/dl.

Conclusion: The aGLP-1 are a valuable treatment option for initiation in KT patients with DM2, having significant efficacy in weight loss. More studies with large samples are required to assess its safety in this population highly affected by DM2 and with borderline GFR.

#6674
SAFETY AND EFFICACY OF SODIUM-Glucose coT RANSPORTER 2 INHIBITORS IN KIDNEY TRANSPLANT PATIENTS WITH TYPE 2 OR POST-TRANSPLANT DIABETES
Luis Alberto Vigara Sánchez1, Marta Alonso2, José Manuel Amaro2, Florentino Villagómez Fernández, Myriam Eady Alonso1, María Gabriela Sánchez Márquez2, María Belén García Jiménez2, Cristhian Orellana2, Teresa García3 and Auxiliadora Mazuecos2
1Jerez de la Frontera University Hospital, Department of Nephrology, Jerez de la Frontera (Cádiz), Spain, 2Puerta del Mar University Hospital, Department of Nephrology, Cádiz, Spain and 3Puerto Real University Hospital, Department of Nephrology, Puerto Real (Cádiz), Spain

Background and Aims: Diabetes mellitus (DM) is a complication in kidney transplant (KT) patients, leading to a higher cardiovascular mortality and graft loss. Therapies such as sodium-glucose cotransporter 2 inhibitors (SGLT2i) have been a cardio-protective and nephroprotective effect and may offer benefits in KT. The aim of our study is to describe the effectiveness and safety of SGLT2i in KT patients.

Method: Retrospective cohort study of KT with DM who started SGLT2i in three Spanish hospitals (Puerta del Mar University Hospital, Jerez de la Frontera University Hospital and Puerto Real University Hospital) between May 2018 and December 2020. Clinical and demographic variables were compared patient and kidney allograft outcomes between 31 KTRs who were temporarily switched from MPA to mTOR-I and 67 KTRs who underwent a reduction of MPA dose.

Results: A switch to mTOR-I was performed more often in case of a CMV high-risk status (50% vs. 21%, p = 0.009), CMV primary infection (68.2% vs. 22%, p < 0.001), and more severe leucopenia (median nadir of neutropenia: 0.52 G/L vs. 0.86 G/L, p = 0.023). The median duration of leucopenia was comparable between the two groups (69 vs. 80 days), 9 of 67 KTRs (13%) developed de novo donor-specific antibodies (dnDSA) under reduced MPA compared to 1 of 31 KTRs (3%) under mTOR-I (p = 0.17). Biopsy-proven rejections were comparable between the two groups (1 in each). There was a slight but insignificant improvement of eGFR under mTOR-I compared to MPA (ΔeGFR +17 vs. +7 ml/min/1.73m2, p = 0.13) and no difference in proteinuria.

Conclusion: A temporary switch from MPA to mTOR-I is a feasible and safe strategy to overcome leucopenia, especially in cases of CMV high-risk status and CMV primary infection. No significant adverse effects on kidney allograft outcomes were observed. Development of dnDSA tended to be lower in the mTOR-I group, suggesting that this strategy may have the potential to reduce the risk of allosensitization.

#4364
LEUCOPENIA AFTER KIDNEY TRANSPLANTATION: SWITCHING MYCOPHENOLEATE TO MTOR INHIBITOR APPEARS SAFE AND FEASIBLE TO REDUCE THE RISK OF ALLOSENSITIZATION
Elena Rho, Pascal Bohraus, Thomas Mueller and Thomas Schachter
University Hospital Zurich, Nephrology, Zurich, Switzerland

Background and Aims: Mycophenolate acid (MPA) is a standard component of maintenance immunosuppression after kidney transplantation. MPA, however, increases the risk of leucopenia. In the past, mTOR inhibitors (mTOR-I) in combination with calcineurin inhibitors (CNI), were considered immunologically safe but showed higher mortality in the long term.

Method: We conducted a retrospective single-center study analyzing 98 kidney transplant recipients (KTRs) under standard triple maintenance immunosuppression between 2020 and 2022 who developed leucopenia. We compared patient and kidney allograft outcomes between 31 KTRs who were temporarily switched from MPA to mTOR-I and 67 KTRs who underwent a reduction of MPA dose.

Results: A switch to mTOR-I was performed more often in case of a CMV high-risk status (50% vs. 21%, p = 0.009), CMV primary infection (68.2% vs. 22%, p < 0.001), and more severe leucopenia (median nadir of neutropenia: 0.52 G/L vs. 0.86 G/L, p = 0.023). The median duration of leucopenia was comparable between the two groups (69 vs. 80 days), 9 of 67 KTRs (13%) developed de novo donor-specific antibodies (dnDSA) under reduced MPA compared to 1 of 31 KTRs (3%) under mTOR-I (p = 0.17). Biopsy-proven rejections were comparable between the two groups (1 in each). There was a slight but insignificant improvement of eGFR under mTOR-I compared to MPA (ΔeGFR +17 vs. +7 ml/min/1.73m2, p = 0.13) and no difference in proteinuria.

Conclusion: A temporary switch from MPA to mTOR-I is a feasible and safe strategy to overcome leucopenia, especially in cases of CMV high-risk status and CMV primary infection. No significant adverse effects on kidney allograft outcomes were observed. Development of dnDSA tended to be lower in the mTOR-I group, suggesting that this strategy may have the potential to reduce the risk of allosensitization.
in renal transplant recipients diagnosed with antibody-mediated rejection (AMR).

**Method:** This was a multicenter, open-label, prospective, randomized analysis. The patients were randomized by therapy type (eg, eculizumab infusions or standard of care [SOC]: plasmapheresis/intravenous immunoglobulin). The patients (ie, eculizumab arm: 7 patients, SOC arm: 4 patients) were evaluated for the continued presence of donor-specific antibodies (DSAs) and C4d (staining on biopsy), as well as histologic evidence, using repeat renal biopsy after treatment.

**Results:** The allograft biopsies revealed that eculizumab did not prevent the progression to transplant glomerulopathy. Cases of AMR were diagnosed in the early post-transplantation period in 2 patients (eculizumab arm: 1 patient, SOC arm: 1 patient) and in the late period in 9 patients. Most of the reports show that eculizumab, in combination with other therapeutic measures such as PP and/or IVIG, effectively reversed rejection. However, eculizumab alone could not treat AMR effectively. Only 2 patients in the SOC arm experienced rejection reversal, and no graft losses occurred in either group. After AMR treatment, the DSA titers generally decreased compared to titers taken at the time of AMR diagnosis. There were no serious adverse effects in the eculizumab arm.

**Conclusion:** Eculizumab alone cannot treat AMR effectively and does not prevent acute AMR from progressing to chronic AMR or transplant glomerulopathy. However, it should be considered as a potential alternative therapy because it may be associated with decreased DSA levels.

**EFFECT OF RITUXIMAB DOSE ON INDUCTION THERAPY IN ABO-INCOMPATIBLE KIDNEY TRANSPLANTATION: A NETWORK META-ANALYSIS USING RECENT DATA**

Joon Ho Song, Seun Deuk Hwang and Jaeho Kim

Incheon, Rep. of South Korea

**Background and Aims:** Rituximab is an essential inducible immunosuppressive agent for ABO-incompatible kidney transplantation (ABOi KT). However, studies on the dosage by country and transplant center are lacking. Therefore, we retrospectively investigated the effects of rituximab induction doses on patient mortality, transplant failure and adverse events.

**Method:** We included studies mentioning at least two of the eligible induction doses (200 mg, 200–500 mg, or 500 mg) of rituximab during ABOi KT and associated outcomes such as patient survival, graft failure, and bacterial and viral infections. We performed direct and indirect network meta-analyses using a Bayesian model and ranked different rituximab doses using generational mixed treatment comparisons. Publications from 1970 to 2020 were searched and analyzed using the CENTRAL, MEDLINE, EMBASE, and Science Citation Index Expanded databases. GRADE of network meta-analysis approaches specified four levels of certainty for a given outcome: high, moderate, low, and very low.

**Results:** Among 5378 patients in 25 trials, glomerular filtration rate, graft loss, antibody-mediated rejection, T-cell-mediated rejection, fungal infection, bacterial infection, and CMV infection did not differ between ABOi groups treated with different doses of rituximab. The effect on mortality was significantly higher in the rituximab 200-500 mg and rituximab 500 mg groups (odds ratio [OR] 2.4, 95% Crl: 1.5-7.4 and OR 1.8, 95% Crl 1.2-11.2). The incidence of BK virus was significantly lower in the rituximab 200 mg group than in the other groups.

**Conclusion:** In ABO-incompatible kidney transplantation, low-dose rituximab is more effective than high-dose rituximab and reduces the risk of serious infection. Due to the small sample size, further randomized controlled trials may be needed to confirm these findings.

**REAL-WORLD EXPERIENCE WITH COVID-19 THERAPY IN KIDNEY TRANSPLANT PATIENTS DURING THEOMICRONVARIANT PERIOD**

Florentino Villanego Fernández, Marta Alonso, Luis Alberto Vigara Sánchez, Maria Eugenia Rodríguez Mateos, Myriam Eady Alonso, Ana García García-Doncel, Maria del Carmen Minguez Mahanes, Maria Elisa Montero Escobar, Oskar Segurado Tostón, Teresa García and Auxiliadora Mazuecos

1Hospital Universitario Puerta del Mar, Pharmacy, Cádiz, Spain, 2Hospital Universitario de Jerez de la Frontera, Nephrology, Jerez de la Frontera, Spain and 3Hospital Universitario Puerta del Mar, Nephrology, Cádiz, Spain

**Background and Aims:** The development of new drugs against SARS-CoV-2 has improved the prognosis of COVID-19. Large studies often exclude transplant recipients or patients with chronic kidney disease, so the experience in kidney transplant (KT) patients is very limited.

**Method:** Retrospective cohort study of KT patients with mild-moderate COVID-19 in our area who were treated from 01/01/2022 to 12/31/2022. The indication to treat was made according to age, post-KT time and comorbidities. The type of drug depended on anti-spike serology and glomerular filtration rate. We did not use nirmatrelvir/ritonavir due to the risk of interactions.

**Results:** During the period of the study, 106 KT (55 women, 51 men) with mild-moderate COVID-19 were treated, with a mean age of 61 years and a KT vintage at the time of infection of 59 [29-186] months. Of them, 37.7% were diabetics and 83% were fully vaccinated prior to the infection. The anti-spike antibody titer prior to the treatment was significantly lower in those patients who received sotrovimab compared to those who did not receive any treatment (p = 0.000).

**Conclusion:** Our results suggest that treatment of mild-moderate COVID-19 in high-risk KT patients may be effective in preventing progression to severe disease requiring admission. The highest rate of progression was observed in those treated with molnupiravir.

**COMPARISON OF COMBINATION OF RITUXIMAB WITH LOW DOSE THYMoglobulin VERSUS LOW DOSE THYMoglobulin ALONE AS INDUCTION AGENT IN RENAL TRANSPLANTATION**

Rajevalochana Parthasarathy, Deepak Selvanathan and S Veena

The Madras Medical Mission Hospital, Chennai, India

**Background and Aims:** Current immunosuppressive therapies and protocols have led to significant improvements in early patient and graft survival rates following kidney transplantation. However full dose rATG induction therapy (7-10 mg/kg) has been associated with increased morbidity. There is not much...
data available on the use of single dose low dose rATG and rituximab, a
Anti CD 20 chimeric antibody in low sensitized Indian transplant recipients.
To compare the efficacy of low dose single dose rATG(1–1.2mg/kg) versus
combination of rituximab with low dose single dose rATG in ABO compatible
low sensitization renal transplant recipients.
Method: Retrospective analysis of all renal transplant recipients between
2010 and 2022 in our center who received low dose rATG(1-1.2mg/kg) or a
combination of single dose rituximab(375mg/m²) and low dose thymoglobulin
were studied. Demographic data, donor characteristics, HLA matches,
infected rejections were collected. Grant function at 3.6 and 12 months post
transplant if available was collected. Data was analysed using SPSS 16.
Results: Of 86 patients studied, 58(67.4%) received single dose of low dose
rATG(1–1.2 mg/kg/day) (Grp 1) and 28 received a combination of single low
dose rATG & Rituximab(375mg/m²)(Grp 2)(32.5%). There was no significant
difference between the Grp 1 and Grp 2 in terms of age, gender, vintage
of diaylsis, PRA status prior to transplant, no of HLA Matches, donor age and
Donor GFR. There were 9(15%) of Acute cellular rejections (ACR) in Group
1 when compared to 8 (28%) in-group 2 (p = 0.263). The number of steroid
resistant ACR were 2 (3%) in Grp 1 when compared to 3 (10%) in Grp 2 (p =
0.365). The number of ABMR were 5(8.6%) in group 1 when compared to
1(3.5%) in grp 2(p = 0.658). 15.5% had graft loss by 1 year in group 1 compared
to none in grp 2 (p = 0.322).CMV and BKV infections were seen in 1 and no pts
and 1 patient in each group respectively.Overall infection rate was 24% when
compared to 46.4% in grp 2 (p = 0.03). The mean eGFR(ml/min/1.73m²)
at the end of 3 months, 6 months and 1 year was 89.5, 69.3, 94 respectively in grp 1
when compared to 92, 69.4 & 84.3 in grp 2. Conclusion: The % of steroid resistant ACR and the number of infections were
higher in the 1 year in the Single low dose rATG+Rituximab induction when
compared to low single dose rATG alone. However ABMR was lower in the
combination grp. Further prospective RCT’s are required to establish the role
of Rituximab in ABO Compatible transplants.

#3722
CARBAPENEM-RESISTENT ENTEROBACTERIACEAE URINARY TRACT INFECTION IN RENAL TRANSPLANT RECIPIENTS: ROLE OF A NOVEL ANTIBIOTIC REGIMEN
Dharmander Bhadauria and Vamsidhar Veeranki
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Nephrology,
Lucknow, India
Background and Aims: Urinary tract infection (UTI), the most common bacterial infection among renal transplant recipients (RTRs), remains a challenge, particularly given the increased incidence of MDR organisms, including Carbapenem-resistant Enterobacteriaceae (CRE). CRE infections were associated with inferior patient and graft outcomes compared to other bacterial infections. Paradoxically, there have been no guidelines on managing CRE in RTRs besides multiple challenges, including the bacteriostatic nature, poor urinary concentration, and dose-limiting adverse effects of various antibiotics. The current study designed and assessed the outcomes of protocol-based therapy consisting of high-dose Meropenem in combination with other antibiotics followed by prolonged oral administration.
Method: This is a single-centre retrospective study conducted in the department of Nephrology and Renal transplantation, Sanjay Gandhi Post

Graduate Institute of Medical Sciences, India, between 1st August 2016 till 31st July 2022. All the RTRs aged ≥ 18 years admitted between 1st August 2016 and
31st July 2018 with symptomatic UTI and a urine culture positive for CRE were included in the study. Patients who received various antibiotics conventionally based on the treating physician’s decision from August 2016 to July 2017 were considered under the Best available treatment (BAT) group, while the Standardized Therapeutic Antibiotic Regimen (STAR) group included patients treated from August 2017 to July 2018. The treatment of the STAR group consisted of a therapeutic phase for at least six weeks (IV therapeutic phase for two weeks total or one week after the clinical recovery, whichever is later + Oral Therapeutic phase for four weeks) followed by an oral chemoprophylaxis phase for three months. Following the treatment of index UTI episodes due to CRE, follow-up both groups’ follow-up data until a minimum of four years were collected. Appropriate statistical tools were applied, and analyses were performed by SPSS software, version 25.
Results: A total of 37 patients fulfilling the inclusion criteria were included in the study, of which 13 patients were under the BAT group, and 24 were treated by the STAR-based protocol. The mean age of the study population was 37.6 ± 12.3 years, and all were males. Most patients (70.2%) had the UTI due to CRE within one-month post-transplant, and the median duration of UTI post-transplant was 6.1 days (IQR: 4.5 – 33). The primary outcome, recurrence rates of UTI at 48-month follow-up among the patients in the STAR group, was significantly lower than those in the BAT group (30.4% vs 77.8%, p = 0.011). The death-censored graft survival was also significantly better among the STAR group than the BAT group (100% vs 75%, p = 0.03) after 48 months. Graft function at 48 months was also better in the STAR group (Serum creatinine-1.4 ± 0.8 mg/dl vs 2.9 ± 2.2 mg/dl, p = 0.007). The patient survival, however, was similar among the two groups (95.8% vs 88.9%, p = 0.47).
Conclusion: Prolonged and combination antibiotic therapy followed by long-term antibiotic prophylaxis significantly reduced the recurrence of UTI due to CRE among the RTRs. Graft function and death-censored graft survival were also considerably better. Hence, the current study may pave the path for future RCTs based on combination antibiotic therapy as a solution to combat the challenge of CRE in RTRs.

#3911
DIETARY OXALIC ACID INTAKE AND PLASMA OXALIC ACID CONCENTRATION IN PATIENTS WITH CHRONIC KIDNEY DISEASE
Wesley Visser1, Gideon Post Hosper2, Annette van Egmund1, Mirjam Laging1, Jeroen Verhoeven3, Sara Baart1, Chris Ramakers1, Dennis Hesselink1, Jacqueline Wetering van de 1, Mariës Reinders1, Ewout Hoorn4, David Severs1 and Joke Roodyn2
1Erasmus MC, Department of Internal Medicine, Division of Dietetics, Transplantation institute, Rotterdam, Netherlands, 2Erasmus MC, Department of Internal Medicine, Transplantation institute, Rotterdam, Netherlands, 3Erasmus MC, Department of Epidemiology and Biostatistics, Rotterdam, Netherlands and 4Erasmus MC, Department of Clinical Chemistry, Rotterdam, Netherlands

Background and Aims: High oxalic acid concentration may be caused by genetic disorders, enteric diseases, but also by kidney insufficiency per se. It may result in kidney oxalic acid stones, kidney function decline, and failure. This study aimed to investigate whether dietary oxalic acid intake influences plasma oxalic acid concentration in a population undergoing kidney transplantation.
Method: Dietary oxalic acid intake was assessed using a Food Frequency Questionnaire. Based on frequency and portion size, average daily oxalic acid intake in the past year and in the last 24 hours was calculated. A blood sample for determination of plasma oxalic acid concentration was drawn on the operation ward before transplantation. For multivariable analysis seventeen recipient related variables were gathered.
Results: 418 patients were included. The median age of the participants was 62
year, 60% were male, all had an eGFR <20 ml/min/1.73 m², and 66% were on dialysis with a median dialysis vintage of 13 months. The median plasma oxalic acid concentration was 32.2 μmol/L (range 4.6-243.2). In 98.3% of patients oxalic acid concentration was above the upper limit of normal. The average oxalic acid intake was 199 mg/day (range 4-1599), while it was 138 mg/day in the last 24 hours before transplantation (range 0-3900). Multivariable linear regression analysis showed that plasma oxalic acid concentrations were significantly higher in recipients with higher average (p<0.001) and last 24 hours oxalic acid intake (p = 0.002), lower age (p<0.001), lower residual diuresis (p<0.001), higher body mass index (p<0.001), longer dialysis vintage (p = 0.032), hemodialysis (p<0.001), and peritoneal dialysis (p<0.001) versus preemptive status.
Conclusion: In pre-kidney transplant patients, plasma oxalic acid concentration is above upper normal limit in 98.3% of patients and is multifactorially determined. As all other factors are not modifiable, the only way to decrease plasma oxalic acid concentration is dietary restriction.

#4776
RENA L RESER V E ASSESSMEN T IN PATIENTS WHO UN D ERWENT DONOR N P HRECTOMY O V ER A 15-YEAR FOLLOW-UP PERIOD AND COMPARISON WITH 2 OTHER PATIENTS

Jelena Tadić1, Nemanja Rancić2, Katarina Obrenčević1, Milorad Radovjević1, Predrag Marić3, Aleksandar Tomić4, Mirjana Mijusković1 and Neven Vavic1

1Military Medical Academy, Clinic for Nephrology, Belgrade, Serbia, 2Military Medical Academy, Center for Clinical Pharmacology, Belgrade, Serbia, 3Military Medical Academy, Clinic for Urology, Belgrade, Serbia and 4Military Medical Academy, Clinic for Vascular and Endovascular Surgery, Belgrade, Serbia

Background and Aims: Since the beginning of living related/non-related transplantation programs, the long-term risks for kidney donors after donor nephrectomy have not been given enough significance. Initially, the emphasis was only on the good health of the living donor at the time of donation, but there was no monitoring of the donor’s health and life quality post-op. In recent years, special attention has been given to kidney donors after living transplantation, as a result of a long-term follow-up and the fact that they are more susceptible to develop certain diseases, e.g. an increased risk of chronic kidney disease (CKD) and terminal renal failure (ESRD).

Method: The study was conducted as a retrospective case-control study. In our study, 243 patients, who were divided into three groups, were analysed. The case group consisted of patients who underwent donor nephrectomy (108 patients), the first control group consisted of patients who were being monitored because of simplex or parapelvic cysts with preserved renal function parameters (40 renal cyst patients with Bosniak classification ≤2) of similar age and sex, while the second control group consisted of patients who underwent a unilateral radical nephrectomy due to kidney cancer in T1bNoMo clinical stage (95 patients).

Results: The kidney donors from the case group were mainly females (60.2%) with the average age of 55.87 years at the time of transplantation. In comparison to the control groups, we observed a statistically significant difference in the radical nephrectomy group of patients, who were, on average, younger Caucasian males, with the average age of 46.84 years. The renal reserve recovery (GFR) was faster in the donor nephrectomy group (85%) than in the radical nephrectomy group, whose recovery was 76.67% of the initial values. Also, the values of serum creatinine (sCr) in the donor nephrectomy group after only one month were very similar to the values of sCr after ten years of follow-up (median was approximately 83 μmol/l). GFR according to the CKD EPI formula was initially the best in the group of patients with cysts, and this trend continued over the 15-year follow-up. After one year, eGFR CKD EPI corresponded to the second degree of renal impairment in both the donor and radical nephrectomy groups, bearing in mind the fact that in the group with radical nephrectomy it was lower than sCr by median of 1.73μmol/l after one year, and that the trend of declining kidney function was maintained even after 15 years of follow-up. On the other hand, in the donor nephrectomy group, after 10 years of follow-up, eGFR CKD EPI was above 65 ml/min/1.73m², i.e. above 60 ml/min/1.73m² after 15 years of follow-up. In contrast, in the group of patients with renal cysts, a reduced kidney function was verified only after 10 years of follow-up - less than 90 ml/min/1.73m², while it was maintained above 80 ml/min/1.73m² even after 15 years of follow-up.

Conclusion: Comparing these three groups, only in the donor nephrectomy group, one patient ended up on chronic hemodialysis treatment (0.92%), while in the other two groups there were no patients with terminal kidney failure. The values of serum creatinine - the median, were the same after 6 months and after 5 years post-op in the donor nephrectomy group (79 μmol/l). The aforementioned findings can help us predict the expected values of serum creatinine after donor nephrectomy in the future. In donors as well as in patients with renal cysts, the reason for higher mortality was not ESRD, but more often it was a sudden cardiac death or a cardiovascular disease. The well-being of the giver must be ensured both in the short and long term, but the potential harmful consequences for the recipient must be determined as well.

Nuttalisa Larparpisarith, Kritsada Pongsakornkuilachat, Attapong Vongsiwatana and Peenida Skulratana

Faculty of Medicine Siriraj Hospital, Mahidol University, Division of Nephrology, Department of Medicine, Bangkok, Thailand.

Background and Aims: The lower humoral immunity response after COVID-19 vaccine in kidney transplant recipients (KTRs) has been reported in several studies. However, the study regarding efficacy of ChAdOx1 nCoV-19 (AstraZeneca) vaccine among various immunosuppressive treatments in Asian population is scarce.

Method: We conducted a cross-sectional study in Siriraj Hospital, Bangkok, Thailand. Adult KTRs who received two doses of the ChAdOx1 nCoV-19 vaccine at intervals of 6 months were enrolled. Anti-SARS-COV-2 S-RBD-IgG antibody (anti-RBD) was assessed at the one month after the second vaccine dose and considered positive if the level ≥ 50 AU/mL. Primary outcome was seropositivity of anti-RBD. Association between type, dose and level of immunosuppressive regimen, and seropositivity of anti-RBD were analyzed. The statistical analysis was performed using SPSS version 23.0.

Results: Between October 2021 and January 2022, 153 KTRs with median follow-up time of 59 (30 – 125) months, were enrolled. Mean age was 49.3 ± 11 years and 61.4% were male. Regimen of tacrolimus (TAC)/mycophenolate mofetil (MPA)/prednisolone (CS), everolimus (ER)/MPA/CS and TAC/ER/CS were prescribed for 92 (60.1%), 23 (15%) and 24 (15.7%) patients, respectively. The anti-RBD ≥ 50 AU/mL after vaccination was observed in 82 patients (53.6%) with median level of 476.7 (129 – 1253.2) AU/mL. Patients received TAC/ER/CS had significantly higher proportion of seropositivity than ER/MPA/CS (95.8% vs 65.2%; p = 0.008) and TAC/MPA/CS regimen (95.8% vs 37%; p < 0.001). Among the seropositive KTRs, the median level of anti-S is significantly highest in TAC/ER/CS treatment when compared to ER/MPA/CS and TAC/MPA/CS group, respectively (1,204 vs 260.7 vs 315.4; p < 0.001). Among KTRs who received tacrolimus, the seropositivity was significantly higher in patients who had tacrolimus trough level < 3 ng/mL (83.3% vs 45.7%; p = 0.014).

Conclusion: The seropositivity of anti-S after vaccination with ChAdOx1 nCoV-19 in KTRs was 53.6% which was lower than general population. KTRs who received TAC/ER/CS regimen had highest immune response after vaccination, which is relatively comparable to healthy control in Thailand. Immunosuppressive regimen should be considered for vaccine dose and schedule in the future.

#5729
HIGHER DAILY PROTEIN INTAKE CAN IMPROVE THE GRAFT FUNCTION OF KIDNEY TRANSPLANT RECIPIENTS IN THE EARLY POSTTRANSPLANT PERIOD

Binqi Yang1, Yuan Liu2, Ye Tao3 and Yunying Shi3

1West China Hospital, Sichuan University, Chengdu, China, department of Nephrology, P.R. China, 2West China Hospital, Sichuan University, Chengdu, China, department of Nutrition, P.R. China and 3West China Hospital, Sichuan University, Chengdu, China, department of Nephrology, P.R. China

Background and Aims: Protein-energy wasting (PEW) is commonly seen among uremic patients, which may still exist after they received kidney transplantation,[1,2] and it is a determining factor in the progression of chronic kidney disease (CKD).[3] The use of immunosuppressants and glucocorticoids after transplantation will also affect the patients’ metabolism and aggravate their malnutrition.[4,5] Adequate daily protein intake (DPI) in the early posttransplant period facilitates the rapid recovery of surgical wounds.[6] However, few studies focused on the impact of DPI on the early recovery of graft function. This study aimed to explore the relationship between DPI and graft function at month 3 posttransplant, which may provide a basis for clinical nutritional regimen of kidney transplant recipients.

Method: This is a retrospective observational study, 176 kidney transplant recipients (KTRs) who underwent kidney transplant in West China Hospital from December 2021 to June 2022 were included and followed up regularly. 24-hour urine urea data were collected at month 3 posttransplant to calculate their DPI. These KTRs were further divided into two groups according to the recommended DPI for KTRs by the 2021 Practice Guidelines for the Nutritional Management of Chronic Kidney Disease,[7] namely high intake group (Group 1, with DPI ≥ 1.4 g/kg·d, n = 66) and low intake group (Group 2, with DPI < 1.4 g/kg·d, n = 110). Laboratory data and posttransplant adverse events within 3 months were recorded. Multiple logistic regression was used to analyze the relationship between DPI and early posttransplant graft function.
Results: Mean DPI levels at month 3 posttransplant were 1.75±0.56 g/kg·d in Group 1 and 0.98±0.24 g/kg·d in Group 2, respectively. There was no significant difference in age, gender, pretransplant body mass index (BMI), dialysis type and time, donor type, or the ratio of delayed graft function (DGF) between the two groups. The levels of estimated glomerular filtration rate (eGFR), body mass index (BMI), hemoglobin (Hb), high-density lipoprotein cholesterol (HDL), and urinary protein at month 3 posttransplant in Group 1 were significantly higher than those in Group 2 (P < 0.005, Fig. 1). No statistical difference was found in the incidence of adverse events between the two groups at month 3 posttransplant. The results of multiple logistic regression analysis showed that higher DPI in the early posttransplant period was a protective factor for graft function after kidney transplantation.

Conclusion: In the early posttransplant period, higher dietary protein intake (DPI ≥ 1.4 g/kg·d) may improve graft kidney function, lipid metabolism, and renal anemia.

EFFICACY OF DESENSITIZATION TREATMENT IN HYPERIMMUNIZED PATIENTS AWAITING A CADAVERIC KIDNEY TRANSPLANTATION
Maria Elena Gonzalez Garcia¹, Maria Ovidia Lopez Oliva¹, Esther Mancebo² and Carlos Jimenezes²
¹Hospital Universitario La Paz, Nephrology, Madrid, Spain and ²Hospital 12 de Octubre, Immunology, Madrid, Spain

Background and Aims: On all kidney waiting lists, patients who have antibodies against more than 80% of a panel reactive antibody (PRA) are difficult to transplant, even with national or regional programs. Desensitization treatment with high-dose intravenous immunoglobulin and rituximab could be offered to patients with a long waiting time for a cadaveric donor to improve their odds of finding a kidney.

Method: Retrospective, single-center study including all hyperimmunized patients on the waiting list for a cadaveric kidney donor who received a desensitization treatment between 2010-2020. To be considered to the desensitization protocol, all the patients must have a PRA above 75% and have been on the waiting list more than 3 years, without any offer. Our treatment was based on the modified Cedars-Sinai Medical Center protocol. Eight hyperimmunized patients on the waiting list for a cadaveric donor kidney transplant (50% male with a mean age of 41.5±16.4 years) received desensitization treatment with intravenous immunoglobulin and Rituximab. Six of the 8 patients (75%) were on renal replacement therapy with hemodialysis and two on peritoneal dialysis (mean time on dialysis 48±14 months). 75% had received a previous transplant. The median PRA calculated was 98%. The time between desensitization and kidney transplantation, the percentage of reactivity against panel cells (PRA) before and after therapy, graft and donor survival, as well as episodes of acute rejection and viral infections were analyzed. The mean follow-up time after transplantation was 67 months.

Results: No patient presented significant side effects to desensitization treatment. Seven of the 8 patients (87.5%) could be transplanted from a cadaveric donor (negative crossmatch test), in a median 8 months after desensitization. No significant changes were observed in the PRA levels. In the immediate post-transplant period, there were 2 graft losses (28.6%) due to non-immunological causes (1 venous thrombosis in a patient with a coagulation disorder and 1 primary graft failure). Creatinine at discharge was 1.6±0.4 mg/dl and 1.4±0.2 a year after the transplant. Five-year censored death graft survival was 100%. Three patients presented viral replication (1 due to cytomegalovirus (CMV), 1 due to polymavirus (BK) and another CMV+BK), which became negative after switching to m-Tor therapy. There were no episodes of acute rejection. No patient developed cancer during the follow-up.

Conclusion: Desensitization treatment with immunoglobulin and rituximab on hyperimmunized patients on the cadaveric waiting list is a safe and effective treatment that increases the chances of achieving a kidney transplant in highly sensitized patients.

DOES IBANDRONATE OR CALCIUM AND VITAMIN D MAINTAIN OR IMPROVE BONE MICROARCHITECTURE IN THE FIRST YEAR AFTER KIDNEY TRANSPLANTATION?
Ruth Strommen¹, Knut Smerud², Niels Meland², Kristin Godang³, Hege Kampen Pihlstrom¹, Anders Asberg¹, Anna Varberg Reisater¹ and Jens Bollerslev³

<image>
Conclusion: BMD in any of the groups, and change in TBS was not significantly correlated with change in lumbar spine. These patients could benefit from anti-resorptive therapy.

Method: We analyzed TBS changes and potential treatment effects in 179 de novo KTR. 118 of whom had participated in a randomized controlled trial[1] evaluating the effect of ibandronate (active/placebo) on top of calcium and vitamin D in the first year after kidney transplantation. Trial participants were compared to 61 patients transplanted in the same time-period, meeting the same study inclusion criteria, but receiving no specific bone-directed treatment. Correlations between changes in TBS and lumbar spine BMD were investigated. We used ANOVA and ANCOVA with adjustment for baseline TBS values to evaluate the potential effects of calcium and vitamin D with/without concomitant ibandronate on TBS 12 months after transplantation, as compared to no treatment.

Results: Mean TBS increased in all groups from baseline to 12 months after transplantation (2.1% for ibandronate/calcium/vitamin D, 2.7% for calcium/vitamin D, and 3.4% for no treatment). Adjusting for baseline TBS, there were no significant differences in TBS at 12 months, neither with overall comparison (p = 0.377) nor when comparing the groups pairwise. The correlation between TBS and BMD was weak (r = 0.170, p = 0.02) at baseline, and change in TBS was not significantly correlated with change in lumbar spine BMD in any of the groups.

Conclusion: In a group of de novo KTR with reasonably well-preserved bone mass, it does not appear that one year of treatment with ibandronate or calcium and vitamin D significantly affects bone quality as measured by TBS. We found surprisingly weak correlation between changes in TBS and BMD over the study period, indicating that these measurements reflect different aspects of bone integrity and metabolism. This study strengthens the view that focus should be on identifying KTR at high risk of fracture at time of transplantation, as these patients could benefit from anti-resorptive therapy.

REFERENCE

Increased serum levels of tacrolimus (\(n = 3.82^{±0.94}\)) were observed in patients on DOACs as compared to patients on AVK, who had similar clinical presentation. There was no difference in terms of eGFR decline from start to long-term follow-up. There were no thromboembolic events among patients treated with DOACs or AVK.

Cyclosporin levels were stable at serial evaluation during 18-month follow-up. There were no differences observed in terms of renal function and serum levels of immune modulating agents between patients treated with DOACs and AVK.

Conclusion: DOACs are a potential therapeutic option among kidney transplant recipients treated with immune modulating drugs. Careful evaluation of immunomodulating agent levels during the first two weeks of therapy should be recommended. No difference in terms of bleeding, thromboembolic events and renal function decline was found when comparing with avk therapy.

THE RELATIONSHIP OF BONE MINERAL DENSITY AND VITAMIN K IN RENAL TRANSPLANT PATIENTS

Merve Şentürk1, Sla Catá2, Ilay Berke Mentese3, Burkay Kaya2, Dilek Barutcu Atas3, Murat Tugcu3, Ebru Asicroglu3, Izzet Hakki Arikan3, Z. Serhan Tuglular3 and Arzu Velioğlu4

1 Marmara University School of Medicine, Internal Medicine, Istanbul, Turkey, 2 Marmara University School of Medicine, Istanbul, Turkey and 3 Marmara University School of Medicine, Nephrology, Istanbul, Turkey

Background and Aims: Kidney transplantation is the best treatment for end-stage renal disease (ESRD). Osteoporosis is a common health problem in kidney transplant recipients. It is known that the risk of bone fracture increases by 30% in the first 3 years after transplantation in kidney transplant recipients. Vitamin K is a cofactor involved in the activation of osteocalcin. This protein plays a role in bone mineralization. Currently, vitamin K cannot be measured directly from blood samples, and markers such as proteins induced in the activation of osteocalcin (PIVKA-II) and undecarboxylated osteocalcin (ucOC) are used for indirect measurement of vitamin K. In our study, we aimed to investigate the relationship between vitamin K and osteoporosis by measuring serum PIVKA-II, ucOC and BMD in kidney transplant recipients.

Method: It was a cross-sectional observational study. Patients were selected from kidney transplant patients over 18 years old. A control group was formed from dialysis patients over the age of 18. For vitamin K levels, PIVKA-II and ucOC levels were measured in serum samples taken from patients. The relationship between vitamin K markers, bone mineral densitometry and the risk of major osteoporotic fracture calculated by FRAX in kidney transplant patients. It is known that the risk of bone fracture increases by 30% in the first 3 years after transplantation in kidney transplant recipients. Vitamin K is a cofactor involved in the activation of osteocalcin.

Results: 68 kidney transplant patients and 20 dialysis patients followed in our clinic were included in this study. As results, it was observed the increased risk of osteoporosis in postmenopausal women followed in our clinic were included in this study. As results, it was observed the increased risk of osteoporosis in postmenopausal women followed in our clinic were included in this study. As results, it was observed the increased risk of osteoporosis in postmenopausal women followed in our clinic were included in this study. As results, it was observed the increased risk of osteoporosis in postmenopausal women followed. It was a cross-sectional observational study. Patients were selected from kidney transplant patients over 18 years old. A control group was formed from dialysis patients over the age of 18. For vitamin K levels, PIVKA-II and ucOC levels were measured in serum samples taken from patients. The relationship between vitamin K markers, bone mineral densitometry and the risk of major osteoporotic fracture calculated by FRAX in kidney transplant patients. It is known that the risk of bone fracture increases by 30% in the first 3 years after transplantation in kidney transplant recipients. Vitamin K is a cofactor involved in the activation of osteocalcin.

Conclusion: In our study, it has been proven that as the vitamin K level decreases in kidney transplant patients, the vertebral bone mineral density decreases while the risk of osteoporosis increases. This result shows that vitamin K replacement may have positive effects on bone metabolism.

E4 - COMPLICATIONS IN TRANSPLANTATION

#2846 DEVELOPMENT OF THE JAPANESE VERSION OF THE BASEL ASSESSMENT OF ADHERENCE TO IMMUNOSUPPRESSIVE MEDICATIONS SCALE
Akihiro Kosoku1,2,1, Tamioaki Iwai1, Hiroo Masuda1, Kazuya Kabel1, Shunji Nishide1, Keiko Maeda2, Yuki Yoshikawa1, Yasutaka Nakamura2, Sabina De Geest2,3, and Junji Uchida1

1Osaka Metropolitan University Graduate School of Medicine, Urology, Osaka, Japan, 2Meijibashi Hospital, Urology, Matsubara, Japan, 3Osaka City General Hospital, Urology, Osaka, Japan, 4Osaka Metropolitan University Hospital, Nursing, Osaka, Japan, 5Shitennoji University, Nursing, Habikino, Japan, 6Osaka Metropolitan University Hospital, Pharmacy, Osaka, Japan, 7University of Basel, Public Health, Basel, Switzerland and 8Katholieke Universiteit Leuven, Public Health and Primary Care, Leuven, Belgium

Background and Aims: One of the major barriers for long-term transplant outcomes in kidney transplant recipients is medication non-adherence, which is a risk factor for de novo donor-specific antibody development leading to antibody-mediated rejection and graft loss. Identifying non-adherent patients is the first step in minimizing the risk of complications of medication non-adherence. However, to date, there is no validated Japanese self-report instrument to evaluate the MA for transplant patients. This study aimed to determine the reliability and validity of the Japanese version of the Basel Assessment of Adherence to Immunosuppressive Medications Scale (J-BAASIS).

Method: We conducted a single-center cross-sectional study for kidney transplant recipients who visited our hospital. The eligible and willing participants were randomly assigned to two groups, the J-BAASIS group and the J-BAASIS+MEMS group, with random numbers generated by computer. All participants filled out a questionnaire including the J-BAASIS (the first survey). They filled out a questionnaire again including the J-BAASIS in similar conditions during their following outpatient visit 4-6 weeks later (the second survey). The participants in the J-BAASIS+MEMS group took the methylprednisolone tablets daily using the MEMS until the second survey. We analyzed the reliability (test-retest reliability and measurement error) and validity of the J-BAASIS (concurrent validity with the medication event monitoring system (MEMS) and the 12-item Medication Adherence Scale) referring to the COSMIN Risk of Bias tool.

Results: A total of 106 kidney transplant recipients (the J-BAASIS group, 56; the J-BAASIS+MEMS group, 50) were included in this study. In the analysis of test-retest reliability, Cohen’s kappa coefficient was 0.62. In the analysis of measurement error, the positive and negative agreement were 0.78 and 0.84, respectively. In the analysis of concurrent validity with the MEMS, sensitivity and specificity were 0.84 and 0.90, respectively. In the analysis of concurrent validity with the 12-item Medication Adherence Scale, the point-biserial correlation coefficient for the “medication compliance” subscale was 0.38 (p<0.001).

Conclusion: The J-BAASIS was determined to have good reliability and validity. Using the J-BAASIS to evaluate medication adherence may help clinicians to identify non-adherent transplant patients and institute appropriate corrective measures to improve transplant outcomes. Moreover, this study, which demonstrated the concurrent validity with the MEMS, the gold standard for measuring medication adherence, further strengthens the evidence for the psychometric properties of the original BAASIS.

#3571 GROWTH PATTERNS IN PEDIATRIC KIDNEY TRANSPLANT RECIPIENTS: A RETROSPECTIVE SINGLE CENTER STUDY
Varvara Askiti, Georgia Malakasioti, Evangelia Gole and Andromachi Mitsioni

Children’s Hospital “P&A Kyriakou”, Pediatric Nephrology Department, Athens, Greece

Background and Aims: Attainment of a normal adult height remains a great challenge in the care of children with end stage kidney disease. Moreover, the incidence of overweight and obesity increases post kidney transplantation (KT). We aimed to describe growth parameters and predictive factors in children post KT.

Method: We retrospectively reviewed the records of 28 children who underwent KT in our center between 2002-2022. Height (hSDS) and body mass index (BMIzSDS) z-scores at various time points and possible predictors were assessed.

Results: Median age at KT was 11.2 years (5.3-14), 20 were male, mean time on dialysis was 5.95 years. KT from a living donor (LRD) was performed in 18 patients. Mean follow-up time was 4.88 (1-10) years. rhGH was administered pre-KT in 15/28 patients and in 3 post KT. Following the first year post KT, steroid-free, alternate day and daily steroid regimes were adopted for 9, 11 and 8 patients, respectively. Mean hSDS at the time of KT, one year after and at last visit were -1.76, -1.87, and -1.77 (p<0.005). Mean BMIzSDS at the respective time points were 0.13, 0.65 and 0.05 respectively (p<0.05). At last visit, 29% and 17% of children showed moderate and severe height deficit. hSDS at last visit was associated with preoperative hSDS, whereas difference between hSDS pre and last visit post KT (ΔhSDS) was associated with the type of KT (mean ΔhSDS for LRD and DDT -1.45 (95%CI -1.87, -1.03) and -2.66 (95%CI -3.4, -1.93) respectively, p = 0.002) and steroid regime (mean ΔhSDS for daily and alternate day steroid treatment -0.39 (95%CI -0.77, -0.003) and 0.55 (95%CI -0.07, 1.17) respectively, p = 0.037). There was no association between ΔhSDS and rejection episodes or rhGH administration pre-KT. At the time of KT and at last visit 25% and 10.7% were overweight, respectively, whereas only 1 patient was obese preoperatively but none at last visit. The overall incidence of overweight and obesity had reduced at last visit compared to pre-KT (p = 0.01).

Conclusion: Linear growth post KT remained limited, resulting in short stature in nearly half of children. Strategies to improve height post pediatric KT could include height optimization pre-KT, steroid withdrawal/avoidance protocols, and LRD KT.

#3654 ABO-INCOMPATIBLE KIDNEY TRANSPLANTATION LOWERS INCIDENCES OF DE NOVO DONOR-SPECIFIC ANTIBODIES AND CHRONIC ANTIBODY-MEDIATED REJECTION
Lukas Weidmann, Kai Castrezzana Lopez, Nicolas Schmid, Thomas Mueller and Thomas Schachtner

University Hospital Zurich, Nephrology, Zürich, Switzerland

Background and Aims: ABO-incompatible kidney transplantation has been associated with an increased risk for antibody-mediated rejection (ABMR) and early graft loss attributable to isoagglutinins. Its impact on the development of de novo donor-specific HLA antibodies (DSA) and DSA-induced chronic ABMR, however, remains less well studied.

Method: We analyzed 297 kidney transplant recipients (KTRs) who underwent living donor transplantation at the University Hospital Zurich from 2009 to 2021. 58 ABO-incompatible (iABO) KTRs were compared to 239 ABO-compatible (cABO) KTRs concerning the development of de novo donor-specific antibodies (DSA) and antibody-mediated rejection (ABMR). ABO desensitization was performed using rituximab and antigen-specific immunoadsorption. The HLA-derived epitope-mismatches were calculated per HLA-locus and in total using the Predicted Indirectly Recognizable HLA-Epitope (PIRCH-E-II) algorithm. High-resolution re-typing was performed from protocol kidney allograft biopsies if necessary.

Results: The incidence of TCMR/ABMR in the first post-transplant year was comparable between iABO KTRs (19%) and cABO KTRs (13%; p = 0.207). De novo DSA were detected in only 1 of 58 iABO KTRs but 12 of 239 cABO KTRs in the first post-transplant year and 2 of 58 iABO KTRs but 50 of 239 cABO KTRs in the long-term follow-up (p = 0.001). ABMR was diagnosed in only 1 of 58 iABO KTRs but 28 of 239 cABO KTRs after the first post-transplant year (p = 0.021). iABO kidney transplantation decreased the risk of de novo DSA development (HR 7.222, CI 1.755-29.722, p = 0.006) and ABMR (HR 7.362, CI 1.000-54.239; p = 0.050) after the first-post-transplant year independent from the presence of preformed DSA. Total PIRCH-E-II scores and PIRCH-E-II scores per locus were not associated with the development of de novo DSA in all 297 living-donor KTRs (p<0.05).

Conclusion: Our findings suggest that iABO kidney transplantation is associated with a lower incidence of de novo DSA and ABMR in the long term, independent from the HLA-derived epitope mismatch load. Whether this protective effect offers new therapeutic options against kidney allograft injury needs to be investigated in future studies.

Abstracts
Post-transplant diabetes mellitus (PTDM) is a frequent complication after kidney transplantation (KT), with an incidence between 20-30%. PTDM increases the risk of cardiovascular disease, which is one of the main causes of death with functioning grafts. The pathophysiology of PTDM involves beta-cell dysfunction, with impaired insulin secretion and insulin resistance overlaid immunosuppression accelerating preexisting damage. The major risk factor in the post-transplant period is immunosuppression therapy, such as steroids, calcineurin inhibitors (CNI), and mTOR inhibitors (mTORi). It is also a major modifiable risk but must be balanced with rejection risk. This systematic review aims to investigate the effect of different immunosuppressive regimens on the risk of PTDM incidence.

Methods: Relevant studies were obtained from a systematic literature search. We searched MEDLINE and CENTRAL (Cochrane Central Register of Controlled Trials) until 15 May 2022. We searched randomized controlled trials (RCT) including KT recipients receiving any immunosuppression and reporting PTDM outcomes. The definition of PTDM was whatever was used by the authors. Meta-analysis was done by pooling data for calculating the relative risks (RR) of the outcome by comparing different immunosuppression strategies.

Results: We identified 1,848 reports. After removing duplicates and screening titles and abstracts 156 full-text reports were assessed. We finally included 52 studies. Eight RCTs reported the outcome of PTDM using different induction therapies at ≤ 5 years post KT, with a total inclusion of a population of 1,495 recipients. The meta-analysis of all studies did not show differences by comparing different doses or formulations of the same drug (Table 1). The cumulative incidence of PTDM was 14% (95% CI [11.4-16.9]). The estimated incidence of PTDM after 2 years post KT showed an increased risk of PTDM (15 studies, 3,200 participants, RR 1.60, 95% CI [1.4-2.23], p < 0.01). We found 39 RCTs that reported PTDM outcomes in KT receiving CNI. In de novo KT, there was an increased risk of developing PTDM with tacrolimus rather than with ciclosporin (26 studies, 5,635 patients, RR 1.71, 95% CI [1.38-2.11], p < 0.01) after ≤ 5 years post KT. There were no differences comparing different doses or tacrolimus formulations. When belatacept was compared to CNI we found a 38% reduction at 1-year post KT in the risk of developing PTDM (6 studies, 2,100 participants, RR 0.62, 95% CI [0.42-0.91], p = 0.02).

Conclusion: A higher risk of PTDM was observed in patients receiving TAC vs GA, and mTORI inhibitors. Belatacept showed a 38% reduction in PTDM compared to CNI. However, the risk of PTDM should be balanced with the risk of rejection.

COMMON VARIABLE IMMUNODEFICIENCY WITH A TNFRSF13B GENE MUTATION IN A KIDNEY AND PANCREAS TRANSPLANT RECIPIENT: WHAT SHOULD WE AIM FOR?

Miguel Coimbra1,2, Joana Freitas2, Renata Carvalho2, Jose Francisco2, Sara Vilela2, Catarina Isabel Ribeiro2, José Silvano2, Sofia Pedroso2, Manuela Almeida2, Jorge Malheiro2 and La Salete Martins2

1Hospital Espírito Santo de Évora, E.P.E., Nefrologia, Évora, Portugal and 2 Centro Hospitalar Universitário de Santo António, Nefrologia e Transplante, Porto, Portugal

Background and Aims: Common Variable Immune Deficiency (CVID) is a primary immunodeficiency disorder, where genetic defects are commonly present, with hypogammaglobulinemia (typically IgG) and increased susceptibility to recurrent infections, autoimmune disorders, granulomatous diseases and malignancy. It can also potentially lead to nephropathy, with increased risk of proteinuria and metabolic acidosis, higher risk of acute tubular injury caused by Immunoglobulin replacement therapy, and the data available in current literature shows a higher incidence of tubulointerstitial nephritis and membranous glomerulopathy, with IgG deposits on immunofluorescence in most cases. Our aim is to report the challenges of a kidney and pancreas transplant in a recipient with chronic kidney disease and a primary immunodeficiency disorder, to outline an immunosuppression strategy with potential alternatives, and to report on the short-term outcomes.

Case Report: Here-in, we report the case of a 27-year-old patient, with type 1 diabetes mellitus, diagnosed with end-stage chronic kidney disease, who has a history of chronic inflammatory response dysregulation, with chronic monoarthritis, persistent elevation of inflammation markers, recurrent infections and low IgG levels. Genetic screening revealed a heterozygous pathological mutation in TNFRSF13B gene, and a Variant of Uncertain Significance (VOUS) in BACH2 gene. At 24 years-old, she experienced a high-risk pregnancy with HELLP syndrome, and serum creatinine and non-nephrotic proteinuria progressively worsened after postpartum. A native kidney biopsy revealed diabetic nephropathy, with C3 and IgG pseudolinar deposits on immunofluorescence. Eventually, disease progression led to hemodialysis induction. 10 months later, she received a kidney and pancreas cadaveric transplant from a standard criteria donor (SCD). Serum baseline donor creatinine was 0.9 mg/dl, and cause of death was a hemorrhagic stroke. Both donor and recipient had blood group type A (ABO system) and positive cytomegalovirus (CMV) IgG levels. Compatibility analysis showed donor Histocompatibility Leukocyte Antigens (HLA) class I: A 01,32; B08,64; C07,08; and class II: DR 17,07; DQ 02,02; DP 03,45; and recipient HLA class I: A 02,02; B 35,44; C 04,05; and class II: DR 03,04. Flow cytometry showed no receptor class I or class II anti-HLA antibodies. Panel Reactive Antibodies (PRA) test score was 0%, and flow cytometry cross-match (FCCM) was negative. Immunosuppression induction regimen included thymoglobulin, mycophenolate mofetil and prednisolone, with optimal pancreatic graft function. Creatinine at discharge was 2.1 mg/dL. After discharge, maintenance immunosuppression protocol included tacrolimus, mycophenolate mofetil and prednisolone, and pancreas and renal graft function remained successfully stable, with no serious infections until current date.

Discussion: Common variable immunodeficiency with a heterozygous TNFRSF13B gene mutation is associated with increased risk of hypogammaglobulinemia, lymphoma, gastrointestinal cancer and autoimmunity. The VOUS BACH2 gene is also likely pathological, since there have been BACH2 polymorphisms associated with autoimmune endocrine diseases, including Addison's disease, Graves' disease and type 1 diabetes mellitus. A hyper-regulated inflammatory state can accelerate kidney function deterioration, but chronic treatment with corticosteroids should be cautious due to the underlying diabetic nephropathy. After transplantation, recipients with CVID are at higher risk of atypical infections, autoimmune complications and disease recurrence with suboptimal long term graft survival. The evidence of current immunosuppression maintenance regimens is weak due to the paucity of CVID cases described in current literature. In the future, we believe that belatacept could offer benefits in terms of reducing the risk of graft loss or the incidence of serious infectious in a transplant recipient with a primary immunodeficiency disorder. Nevertheless, therapy management should be accomplished in a patient-to-patient basis.

URINARY CXCL9 AND CXCL10 CONCENTRATIONS AND KIDNEY TRANSPLANT INJURY

Ernesta Macioniene1,2, Marius Miglinas1,2, Martynas Simanavicius3 and Monika Vitkauskaite1

1 Vilnius University, Institute of Clinical Medicine, Faculty of Medicine, Vilnius, Lithuania, 2 Vilnius University Hospital Santaros Klinikos, Centre of Nephrology, Vilnius, Lithuania and 3 Life Sciences Center, Vilnius University, Institute of Biotechnology, Vilnius, Lithuania

Background and Aims: Kidney transplant rejection is diagnosed by the kidney biopsy which is an invasive diagnostic method, however, non-invasive biomarkers, distinguishing normal kidney transplant from transplant rejection would be preferred but are lacking. CXC chemokine ligand 9 (CXCL9) and CXC chemokine ligand 10 (CXCL10) are gamma interferon inducible small cytokines. The aim of this study was to evaluate urinary CXCL9 and CXCL10 as potential biomarkers of allograft rejection.

Method: 117 kidney transplant recipients undergoing kidney transplant biopsy (surveillance or indication) were included into this study. Spot urine samples were collected before kidney biopsy for urinary creatinine, CXCL9 and CXCL10 measurement. The ratios of CXCL9 over urinary creatinine and CXCL10 over urinary creatinine were calculated. Kidney biopsies were analyzed according to Banff criteria by an experienced pathologist.

Results: 26 (22.2%) of kidney biopsies were defined as normal histology, 24 (20.5%) – antibody mediated rejection, 9 (7.7%) – T cell mediated rejection, 10 (8.6%) mixed rejection, 5 (4.3%) BK virus nephropathy and 43 (36.8%) were defined as other histological lesions. Average CXCL9/creatinine was 0.408, p = 0.01 and CXCL10/creatinine was 2.47, p < 0.01. ROC curve for CXCL9/creatinine detecting antibody mediated rejection was 0.79, CI 0.67 to 0.90, p < 0.01. ROC curve for CXCL10/creatinine detecting antibody mediated rejection was 0.79, CI 0.64 to 0.94, p < 0.01.

Conclusion: Urinary biomarkers CXCL9/creatinine and CXCL10/creatinine has a potential to distinguish normal renal histology from allograft rejection and correlates to proteinuria at the time of the biopsy.

INDIRECT INSULIN RESISTANCE INDICES AND THEIR CUT-OFF VALUES FOR POST-TRANSPLANTATION DIABETES MELLITUS IN KIDNEY TRANSPLANT RECIPIENTS

Sara Sokooti Oskooei1, Tamas Szili-Torok2, Hiddo Lambers Heerspink1, Robin P.F. Dullaart4 and Stephan J.L. Bakker2

1 University Medical Center Groningen, Nephrology, Groningen, Netherlands, 2 University Medical Center Groningen, Nephrology, Groningen, Netherlands, 3 University Medical Center Groningen, Clinical pharmacology, Groningen, Netherlands and 4 University Medical Center Groningen, Endocrinology, Groningen, Netherlands

Background and Aims: Insulin resistance determination in kidney transplant recipients (KTRs) plays an important role to identify KTRs at risk of post-transplantation diabetes mellitus (PTDM) development. Current methods to measure insulin resistance include the hyperinsulinemic-euglycemic (HIEG) clamp technique, and minimal model approximation of the metabolism of glucose (MMAMG). These methods, however, require considerable time and are expense, complex, and invasive. As a result, indirect insulin resistance indices such as homeostasis model assessment-insulin resistance (HOMA-IR), visceral adiposity index (VAI), lipid accumulation product (LAP), or triglycerides-glucose (TyG) index, are used in epidemiological and clinical studies in the general population due to their simplicity and ease of use. However, it is unknown to what extent those indices may contribute to determine insulin resistance and PTDM development in KTRs. Therefore, this study aimed to investigate the role of indirect insulin resistance indices to determine insulin resistance and PTDM development in KTRs.

Method: We included 472 stable outpatient KTRs (with a functioning graft ≥ 1 year) without diabetes from a prospective cohort study. Crude and multivariable Cox proportional hazards regression analysis were performed to determine whether indirect insulin resistance indices (HOMA-IR, VAI, LAP, and TyG index) were prospectively associated with incident PTDM. We analyzed each measure using receiver operating characteristic (ROC) curve for the development of PTDM. The cut-off value was determined as the value with the highest Youden index score in the specificity dominant area.

Results: During a median 9.6 years [interquartile range (IQR) 6.6–10.2] of follow up, 68 (14%) KTRs developed PTDM. In Cox regression analyses, all indirect insulin resistance indices associated with incident PTDM, independent of potential confounders. ROC curve was 0.764 (95% CI 0.703-0.826) for HOMA-IR, 0.685 (95% CI 0.615-0.757) for VAI, 0.743 (95% CI 0.678-0.808) for LAP, and 0.698 (95% CI 0.629-0.766) for TyG index, with no significant difference between them (p = 0.05). The cut-off values with their corresponding sensitivity and specificity for each indices are presented in Table 1. To test this cut-off value, the association between the indices and incident PTDM was examined by using each index as a categorical variable (HOMA-IR < 2.47 vs ≥ 2.47; VAI < 4.01 vs ≥ 4.01; LAP < 87.04 vs ≥ 87.04; TyG index < 4.94 vs ≥ 4.94). Indirect insulin resistance indices as a categorical variable predicted incident PTDM independent of age, sex, smoking, time to transplantation, systolic blood pressure, eGFR, and medication.

Conclusion: Indirect insulin resistance indices could be used to predict incident PTDM in KTRs. In addition to HOMA-IR, insulin-free surrogates of insulin resistance might serve as useful methods to identify KTRs at risk for PTDM development.

β-2-MICROGLOBULIN AND β-TRACE-PROTEIN DO NOT IMPROVE ESTIMATION OF GFR IN KIDNEY TRANSPLANT RECIPIENTS COMPARING TO CREATINEIN AND CYSTATIN C

Nathalie Kure1, Nicoline Krostrup1, Mihai Oltean3, Bente Jespersen1, Henrik Birn1,3 and Marie Bodilsen Nielsen1,3

1 Aarhus University Hospital, Department of Renal Medicine, Aarhus N, Denmark, 2 Copenhagen University Hospital, Rigshospitalet, Department of Nephrology, København, Denmark, 3 Sahlgrenska University Hospital, The Transplant Institute, Gothenburg, Sweden, 4 Aarhus University Hospital, Department of Clinical Medicine, Aarhus, Denmark and 3 Aarhus University Hospital, Department of Renal Medicine, Aarhus N, Denmark

Background and Aims: Precise estimates of glomerular filtration rate (eGFR) are important in kidney transplant recipients (KTRs). Current eGFR formulas based on plasma creatinine and/or cystatin C are associated with significant bias. We investigated whether race free formulas based on plasma β-2-microglobulin and/or eGFR-β-2-microglobulin performed better than formulas based on creatinine and cystatin C in a Scandinavian cohort of KTRs.

Method: We included samples and data from the randomised, controlled trial CONTEXT. eGFR was measured by plasma clearance of [51Cr]-EDTA or iodothalamate. eGFR was calculated using the new race-free CKD-EPI eGFR-creatinine and/or cystatin C (2021) formulas as well as the CKD-EPI eGFR-β-2-microglobulin and/or eGFR-β-trace-protein formulas. GFR estimates were evaluated at 3 (n = 82) and 12 (n = 64) months post-transplant using mean bias, precision, and accuracy. Also, formulas were analysed for their ability to correctly classify changes in measured GFR from 3 to 12 months.

Results: At 12 months eGFR-creatinine-cystatin C performed best according to mean bias (−4.54 ml/min/1.73 m²), precision (SD = 8.18 ml/min/1.73 m²) and accuracy (P10 = 47%) among creatinine and cystatin C based formulas (Table 1). Among the β-trace-protein and β-2-microglobulin based formulas, eGFR-β-trace-protein-β-2-microglobulin performed best according to precision (SD = 7.64 ml/min/1.73 m²) and accuracy (P10 = 36%) (Table 1). eGFR-β-trace-protein-β-2-microglobulin and eGFR-creatinine-cystatin C performed similar when comparing residuals (p = 0.481). eGFR-β-trace-protein, eGFR-β-trace-protein-β-2-microglobulin and eGFR-creatinine-cystatin C performed best in correctly classifying changes in mGFR from 3 to 12 months.

Conclusion: β-trace-protein and β-2-microglobulin do not improve the measurement of GFR compared to creatinine and cystatin C based formulas in KTRs.

DSA-NEGATIVE MICROVASCULAR INFLAMMATION IN KIDNEY TRANSPLANT BIOPSIES: GENE EXPRESSION COMPARISON WITH NATIVE AND TRANSPLANT KIDNEY CONTROLS

Anna Buxeda1,2, Ivy Fixsen1, Ian Gibson1, Chris Wiebe4, Peter Nickerson3, Patricia Campbell1, Natalia Inmaculada Polanco Fernandez3, Marta Crespo2, Michael Mengel1 and Benjamin Adam1

1 University of Alberta Hospital, Laboratory Medicine and Pathology, Canada, 2 Hospital del Mar, Nephrology, Barcelona, Spain, 3 University of Manitoba, Pathology, Canada, 4 University of Manitoba, Internal Medicine, Canada and 5 Hospital 12 de Octubre, Nephrology, Madrid, Spain

Background and Aims: Microvascular inflammation (MVI) in kidney transplant (KT) biopsies from patients without detectable anti-HLA donor-specific antibodies (DSA) presents a diagnostic and therapeutic dilemma. This study aimed to further understand the significance of these changes by characterizing their molecular phenotype compared to other native and transplant kidney biopsies.

Method: The NanoString B-HOT panel (770 genes) was used to measure the expression of six literature-derived gene sets in 195 archival FFPE kidney biopsies from four centers, including transplant biopsies with MVI (g + p ≥1c) but no detectable DSA (MV1, n = 47), antibody-mediated rejection with DSA (ABMR, n = 42), pure T-cell mediated rejection without DSA (TCMR, n = 25), mixed MVI and TCMR without DSA (MV1+TCMR, n = 47), normal implant biopsies (Normal, n = 11), and native kidney biopsies with either endocapillary proliferative glomerulonephritis (GN, n = 12) or minimal change disease (MCD, n = 11). The evaluated gene sets included transcripts previously associated with ABMR, DSA (DSAST), endothelial injury (ENDAT), TCMR, early injury, and late injury. Gene expression was compared between groups using principal component and class comparison analyses.

Results: Principal component analysis demonstrated significant molecular overlap between sample groups (Fig. 1A). However, gene set analysis showed lower expression of ABMR-related, DSAST (Fig. 1B), and ENDAT gene sets in DSA-negative MVI compared to ABMR. DSAST and ENDAT gene set expression was similar between MV1, MV1+TCMR, and TCMR groups; but higher than native biopsies (p ≤0.002). TCMR and early injury gene set expression was higher in TCMR than all other groups (p ≤0.002), except MV1+TCMR. Late injury gene set expression was lower in MV1 compared to ABMR, MV1+TCMR, and TCMR groups (p ≤0.031); but higher than the Normal and MCD groups (p ≥0.016).

Abstracts
Figure 1:

Conclusion: These results suggest that DSA-negative MVI displays a lower expression of ABMR-related genes than ABMR, but similar to MVI, TCMR and higher than native kidney biopsies with or without glomerulonephritis. Further work is underway to evaluate the potential role of non-HLA DSA and recognition of missing self in these cases.

ISOLATED GLOMERULITIS IS STRONGLY ASSOCIATED WITH THE ABSENCE OF ANTIBODY-MEDIATED REJECTION BY MOLECULAR DIAGNOSTICS

Nicolas Schmid¹, Lukas Weidmann¹, Seraina von Moos¹, Ariana Gaspert¹, Birgit Helmchen⁴, Thomas Mueller⁴ and Thomas Schachtner⁴

¹University Hospital Zurich, Division of Nephrology, Zurich, Switzerland and ²University Hospital Zurich, Institute of Pathology, Zurich, Switzerland

Background and Aims: According to the 2018 Banff classification, the Molecular Microscope Diagnostic System (MMDx) is indicated in cases when histology is insufficient to diagnose antibody-mediated rejection (ABMR) due to an absence of diagnostic criteria groups 2 and/or 3. The impact of isolated glomerulitis (g > 0, ptc0) on the likelihood of ABMR diagnosis by the MMDx appears critical to the implementation of this new biomarker.

Method: We analyzed 251 kidney allograft biopsies by histology and molecular diagnostics at the University Hospital Zurich from October 2018 to November 2022. Histologic findings were classified concerning the absence of (1) diagnostic criteria groups 2 and 3 (n = 18), (2) diagnostic criteria group 2 only (n = 18), and (3) diagnostic criteria group 3 only (n = 28). In addition, cases with histologically proven ABMR were used for comparison (n = 65). High-resolution re-typing was performed from the kidney allograft biopsies if necessary.

Results: The MMDx diagnosed ABMR in 1 of 18 cases (6%) with absent diagnostic criteria groups 2 and 3, 4 of 18 cases (22%) with absent diagnostic criteria groups 2, and 19 of 28 cases (68%) with absent diagnostic criteria groups 3. On the contrary, MMDx confirmed the diagnosis of ABMR in 42 of 65 cases (65%) with histologically proven ABMR but did not in 23 of 65 cases (35%). Among 28 cases with absent diagnostic criteria group 3, only 2 of 19 cases (11%) with ABMR by MMDx but 6 of 9 cases (67%) with no ABMR by MMDx showed isolated glomerulitis (p = 0.0048). Among 65 cases with histologically proven ABMR, only 7 of 42 cases (17%) with ABMR by MMDx but 14 of 23 cases (61%) with no ABMR by MMDx showed isolated glomerulitis (p < 0.001). Overall, 14 of 65 cases (21%) with isolated glomerulitis showed ABMR diagnosis by MMDx.

Conclusion: Isolated glomerulitis is strongly associated with the absence of ABMR by MMDx not only when diagnostic criteria group 2 is missing but also when diagnostic criteria 3 is missing or ABMR is proven by histology. Our results may help to guide the indication for MMDx in clinical practice. However, the clinical significance of these results needs further investigation.

EVOLUTION OF MONOCLONAL GAMMOPATHY OF UNCERTAIN SIGNIFICANCE IN KIDNEY TRANSPLANT RECIPIENTS

Celia González-García, Raquel Berral, Paúl Hernández, Marta Rivero Martínez, Lucía Cordero García-Galán, Aída Frias González, Julio Francisco Colina García, Sergio Huerga Lozano, Ángel Sevillaño, Justo César Sandino Pérez and Enrique Morales

University Hospital October 12, Nephrology, Madrid, Spain

Background and Aims: Monoclonal gammopathy of uncertain significance (MGUS) is a frequent condition with an estimated prevalence of 3% in people over 50 years of age in the general population. Nowadays, more kidney transplants (KT) are performed in a population susceptible to present MGUS, and the evolution of this entity in KT recipients is currently unknown.

Method: We carried out a retrospective study of a cohort of KT recipients diagnosed with MGUS between 1996 and 2020, including patients with MGUS identified prior to kidney transplantation or during follow-up. We describe baseline, kidney transplantation, and hematological characteristics, analyzing the evolution of the hematological parameters according to the moment of appearance of MGUS.

Results: A total of 51 patients were included; in 28 (54.9%) MGUS appeared before transplantation, and in 23 (45.1%) after transplantation. Thirty-two (62.7%) were male, with glomerular pathology in 17 (33.3%) as the leading cause of chronic kidney disease. Hypertension (90.2%) and diabetes (27.5%) were the most common comorbidities. At renal transplantation, the median age is significantly higher in the pre-transplant MGUS group (62 years [IQR 54-66]) vs. 48 years [IQR 40-68]; p = 0.04). This group had a higher induction immunosuppression load than the post-transplant MGUS group (p = 0.01) due to a greater incidence of immunized KT recipients (p = 0.05). There were no differences in rejection, infections, or post-transplant neoplasia between both groups; however, higher renal graft loss was observed in the post-transplant MGUS group (10.7% vs. 43.5%; p = 0.02), probably explained by a longer follow-up time in this group. The most detected paraprotein was IgG (60.8%) and lambda light chain (51%), with a median blood concentration of 0.4 g/dl (IQR 0.2-1.4). In 45.1% of the cases, the paraprotein remained stable; it disappeared in 27.5%, and MGUS progressed to hematological neoplasia in 21.6%, including multiple myeloma, amyloidosis, and post-transplant proliferative syndrome. We did not detect significant differences in the evolution according to the moment of diagnosis of the MGUS (p = 0.7). Twelve renal biopsies were performed during post-transplant follow-up, detecting renal involvement by paraprotein in 5 (9.8%). Only 1 of them (1.96%) was defined as a monoclonal gammopathy of renal significance for not meeting the criteria for malignancy.

Conclusion: Close monitoring of MGUS in KT recipients is still necessary given the possibility of progression to hematological neoplasia, with a non-negligible percentage in our series of patients. Our cohort does not allow us to detect significant differences with an impact on the clinical course of MGUS or KT regarding the moment of the development of MGUS before or after transplantation.

Cytokines IL-6, IFN-γ, TGF-β, and IL-10 were measured using the enzyme-linked immunosorbent assay, and SARS-CoV-2 spike protein-specific IgG titer by chemiluminescent microparticle immunoassay methods.

Results: We found a seroconversion rate of 115/132 (87.12%), with a median antibody titer of 706.40 au/ml (IQR, 215.45-1844.42) in the infection group and 63/78 (80.76%) with a median titer 145.20 (IQR, 80.52-3838.75) au/ml in the vaccinated group. The IL-6, IFN-γ, TGF-β, and IL-10 levels were significantly higher in both, the infection and vaccination groups as compared to the healthy control group. In the infection group, the pro-inflammatory cytokines IL-6 (55.41±24.30 vs. 31.64±16.98 pg/ml; p < 0.001), IFN-γ (91.21±33.09 vs. 61.69±33.28 pg/ml; p = 0.001), and IL-10 (91.31±40.59 vs. 61.69±25.67 pg/ml; p = 0.08) were significantly high in the seroconverter group as compared to non-seroconverter. Anti-inflammatory cytokines TGF-β (730.48±400.47 vs. 765.47±566.39 pg/ml; p = 0.92), and IL-10 (91.31±48.54 vs. 96.73±59.53 pg/ml; p = 0.88) were not significantly different between the seroconverter and non-seroconverter group respectively. Similarly, in the vaccination group, the pro-inflammatory cytokines IL-6 (50.31±25.67 vs. 30.00±11.19 pg/ml; p = 0.002), and IFN-γ (65.70±39.78 vs. 32.14±17.48 pg/ml; p = 0.001) were significantly high in seroconverter post-vaccination compared to non-seroconverter. In contrast, TGF-β (820.96±415.78 vs. 1045.57±204.66; p = 0.046) was elevated in non-seroconverter, and although IL-10 (93.18±35.45 vs. 112.90±59.61 pg/ml; p = 0.11) was not significantly high in non-seroconverter.

Conclusion: Inflammatory cytokines IL-6 and IFN-γ were significantly associated with seroconversion after SARS-CoV-2 infection and vaccination.
correlation between ECMO duration, age (p = 0.012), and LDH (p = 0.041); a significant positive correlation between D-dimer, CRP (p = 0.006) and PaO2 (p = 0.015). We found that post-discharge ventilatory support among survivors was needed in 48.1% and 11.4% (as O2 supplementation or CPAP, respectively).

**Conclusion:** ECMO should be considered for critically ill COVID-19 patients who develop refractory respiratory failure despite standard care.

**#4240** SUCCESSFUL PROPHYLAXIS WITH STROVAC VACCINE AGAINST URINARY TRACT INFECTION AFTER KIDNEY TRANSPLANTATION

Elgun Haziyev

Azerbaijan Medical University, Efferent Therapy and Nephrology Department, Baku, Azerbaijan

**Background and Aims:** Urinary tract infections (UTI) are the most common infections after renal transplantation with an estimated incidence between 10 and 98%. Recurrent urinary tract infections (rUTIs) increase mortality and reduce graft survival after renal transplantation. The present case describes an immunization strategy against bacterial strains after kidney transplantation.

**Method:** We administered urinary tract vaccine for prophylaxis for rUTIs after kidney transplantation. A kidney transplant recipient with 3 or more UTI episodes/year underwent immunization with 3 subcutaneous injections (once a week) of inactivated bacteria-StroVac (follow-up 12 months before to 12 months after immunization). StroVac contains 10 strains of inactivated bacteria (6 types of Escherichia coli, Proteus mirabilis, Morganella morganii, Enterococcus fecalis, Klebsiella pneumoniae). A year later the StroVac Booster was administered once. Urine culture analysis was given every 3 months for a year. Clinical and laboratory comparisons were made. The results were evaluated statistically.

**Results:** Before initiation of prophylaxis, patient had a UTI incidence of 5. The patient had symptoms such as fever, dysuria, or urgency and were positive in urine dipstick examination for pyuria or nitrutria. Vaccination with StroVac significantly reduced the incidence of UTI yielding a mean annual incidence of 1 (p<0.05).

**Conclusion:** StroVac is an effective and lasting non-antibiotic prophylaxis for rUTI, easy to administer with low rates of adverse events and should be offered to patients with rUTI after kidney transplantation.

**#5296** CYTOMEGALOVIRUS INFECTION AFTER COVID-19 IN KIDNEY TRANSPLANT RECIPIENTS: A SINGLE CENTER EXPERIENCE

Gonçalo Pimenta, Sara Queiroz Conde and André Weigert

Centro Hospitalar Lisboa Ocidental, Nephrology, Lisbon, Portugal

**Background and Aims:** Kidney transplant recipients (KTR) have adverse COVID-19 outcomes due to the immunosuppressed status and multiple comorbidities. Cytomegalovirus (CMV) is one of the most frequent opportunistic infections after kidney transplantation. However, data concerning its reactivation after COVID-19 is scarce. Herein, we present a single-center cohort of KTR presenting with CMV infection after COVID-19 and its clinical outcomes.

**Method:** Single-center cross-sectional study including 22 KTR with CMV viraemia detected by quantitative polymerase chain reaction up to 6 months after COVID-19, between 2020 and 2022. Demographic and clinical data were collected from the electronic records.

**Results:** A total of 22 KTR (13 male) were included with a mean age of 55.5±15.5 years and a median Charlson score of 4 (IQR 3-6). Median time after transplantation was 65 months (IQR 12.5-174.5; 3 KTR with <6 months) and only one patient had been submitted to living-donor transplantation. Eight patients received induction therapy with antithymocyte globulin (ATG). At transplantation time, CMV serologic status had been: 50% D+/R+, 13.6% D+-/R- and 4.5% D-/R+. CMV infection prior to COVID-19 had been documented in 6 patients. Concerning COVID-19, severe or critical disease had been reported in 8 patients. Specific therapy had been used in 4 patients: 2 with remdesivir/baricitinib, one with remdesivir and one with molnupiravir. Moreover, immunosuppressive therapy had been adjusted in 11 patients, namely by withdrawing the antimetabolite and increasing steroids (7 patients). Median maximum steroid dose (expressed as equivalents of prednisone dose) had been 40 mg (IQR 20-40) and mean cumulative steroid dose had been 416±317 mg. CMV disease was documented in 8 patients (4 with gastrointestinal involvement) and the mean time of diagnosis after COVID-19 was 10±6 weeks. Maintenance immunosuppression included tacrolimus, antimetabolite and steroid in 12 patients; 6 patients had supratherapeutic levels of tacrolimus at CMV infection diagnosis. Median initial viraemia was 770 copies/mL (IQR 288-4106). Valganciclovir was used in 14 patients (one was already taking it as prophylaxis), ganciclovir in 4 patients and CMV enriched human intravenous immunoglobulin was used in one patient. Nine patients required hospitalization and 2 were transferred to an intensive care unit; one of these 2 patients died. Induction therapy with ATG. CMV serologic status at transplantation time, previous CMV infection, COVID-19 severity or supertherapeutic immunosuppressive drug levels were not associated with CMV infection severity or hospitalization. However, higher maximum steroid dose during COVID-19 was associated with CMV disease (p = 0.038), higher viraemia at diagnosis (p = 0.032) and hospitalization (p = 0.018).

**Conclusion:** CMV infection is a common and clinically relevant complication in KTR. Altered immunologic status after COVID-19 may predispose to this infection. In addition, immunosuppressive therapy adjustments, namely the increase in steroid dosing may be very relevant to favor reactivation of CMV. Larger studies are warranted, but careful monitoring could help identifying risk patients earlier and prophylaxis may be considered when increased corticosteroids are prescribed.

Figure 1: Annual incidence of urinary tract infection (UTI) before (baseline) and after initiation of StroVac vaccination (follow-up). Differences were tested for significance by Wilcoxon test, p < 0.05 was regarded as significant.
CLINICAL AND MOLECULAR SPECTRUM OF V-LESION
Anna Buxeda1,2, Maria José Pérez-Saéz2, Betty Odette Chamoun Huacón1,3, Javier Gimeno1,2, Irina Torres Rodriguez1, Julio Pascual1,2,3, Benjamin Adam2 and Marta Crespo1
1Hospital del Mar, Nephrology, Barcelona, Spain, 2University of Alberta, Laboratory Medicine and Pathology, Edmonton, Canada, 3Hospital Universitari Vall d’Hebron, Nephrology, Barcelona, Spain, 4Hospital del Mar, Pathology, Barcelona, Spain and 5Hospital Universitario 12 de Octubre, Nephrology, Madrid, Spain

Background and Aims: Isolated v-lesion is an increasingly recognized but clinically challenging entity. Some studies suggest that isolated v lesion may be caused by non-alloimmune etiologies such as ischemic injury. We aimed to characterize the allograft outcomes of isolated v-lesions according to post-transplant time (early: 0-1 month vs. late: >1 month) and further understand the significance of this lesion by characterizing its molecular phenotype in comparison with other forms of rejection v+.

Method: The NanoString B-HOT panel (770 genes) was used to measure the expression of six literature-derived gene sets in 92 archival FFPE kidney biopsies from two centers, including transplant biopsies with isolated v-lesion (n = 23), antibody-mediated rejection (ABMR) with v+ (n = 26), pure T-cell mediated rejection (TCMR) with v+ (n = 10), mixed rejection v+ (n = 23), and normal implant biopsies (Normal, n = 10). The evaluated gene sets included transcripts previously associated with ABMR, DSA (DSAST), endothelial injury (ENDAT), TCMR, early injury, and late injury. Gene expression was compared between groups using principal component and class comparison analyses. Death-censored graft survival according to diagnosis and time after KT was assessed.

Results: Isolated v+ early conferred the worst death-censored graft survival one year after the biopsy (40%) when compared to isolated v+ late (100%) or other forms of rejection (≥82%, p = 0.034). The principal component analysis demonstrated significant molecular overlap between sample groups (PC1: 29.4%, PC2: 8.1%). However, gene set analysis showed lower expression of TCMR-related genes in isolated v+ groups compared to TCMR and mixed rejection (p < 0.001). Both isolated v+ early and late had lower ABMR-related genes than ABMR, mixed rejection, and TCMR groups (p ≤ 0.022). Moreover, isolated v+ late showed lower DSAST and ENDAT gene set expression than ABMR (p ≤ 0.046); and lower early injury gene set expression than isolated v+ early, ABMR, TCMR, and mixed rejection (p ≤ 0.026). Late injury gene set expression was highest in TCMR and mixed rejection compared to the other groups (p ≥ 0.034).

Conclusion: These results suggest that early and late isolated v+ lesions display lower expression of TCMR-related genes than TCMR and mixed rejection and lower expression of ABMR-related genes than ABMR. Isolated v+ early confers a bad prognosis and is associated with higher expression of early injury genes compared to isolated v+ late, suggesting a different ethiology.

EBV-NEGATIVE KIDNEY TRANSPLANT RECIPIENTS AND PTLD: THE IMPACT OF INDUCTION THERAPY
Rose Mary Attieh1, Shenhen Mao1, Michael Mao1, Surakit Punghapong1, Wisit Cheungpasitporn2,3, Tambi Jarri1, Hani Wadel1, Burcin Tane1 and Napat Leepaphorn1
1Mayo Clinic Florida, Department of Transplantation, Jacksonville, United States of America and 2Mayo Clinic, Nephrology and Hypertension, Rochester, United States of America

Background and Aims: Individuals who are most susceptible to developing PTLD are those who are EBV-negative and receive organs from EBV-positive donors (EBV R-/D+). The evidence regarding the connection between ATG induction therapy and PTLD is inconsistent. No studies have specifically examined the relationship between ATG use and PTLD in subgroups of EBV-negative transplant recipients (EBV R-). Using the UNOS database, we studied the association between the use of induction agents and PTLD in EBV R-patients.

Method: We analyzed data from 2007 to 2022 of EBV R- patients who underwent their first kidney-only transplant and excluded those who received induction agents other than ATG, basiliximab, or alemtuzumab. We used logistic regression to evaluate the association between induction agents and PTLD.

Results: Of 20,531 recipients, 50.7% received ATG, 19.13% received basiliximab, 13.42% received alemtuzumab, and 16.75% received no induction. The overall PTLD incidence was 2.14%. ATG recipients had higher rates of deceased donor transplants, higher degree of HLA mismatch, longer dialysis vintage, and were less likely to be white, compared to non-ATG recipients. Multivariate analysis showed ATG recipients had a higher risk of PTLD compared to non-ATG (odds ratio = 1.47, p < 0.001). After excluding recipients who did not receive induction, ATG remained a significant independent risk factor for PTLD when compared to recipients who received either basiliximab or alemtuzumab (odds ratio = 1.35, p = 0.007). There was no statistically significant difference in PTLD risk among patients treated with basiliximab, alemtuzumab, or no induction (refer to Table 1).

Conclusion: The use of ATG induction in EBV-negative kidney transplant recipients is associated with a higher risk of PTLD compared to basiliximab, alemtuzumab, and no induction. The risk of PTLD should be considered when choosing induction therapy for this patient population.

**KINETIC ESTIMATION OF GFR AND URINARY CREATININE EXCRETION RATE AS PREDICTORS OF DELAYED GRAFT FUNCTION IN RENAL TRANSPLANTS FROM DECEASED DONORS**

Natividad Calvo Romero, Jesús Dominguez Delgado-Palacios, Marta Calvo Arevalo, Isabel Pérez-Flores, Beatriz Rodríguez Cubillo, María Ángeles Moreno de la Figuera Díaz, María Muñiz Rincón, Arianne Aiffil Meneses, Rómulo Katsu Loayza López and Ana Sanchez Fructuoso

**Hospital Clínico San Carlos, Nephrology, Madrid, Spain**

**Background and Aims:** Delayed graft function (DGF) is a common complication after renal transplant. Definitions of DGF are based on analysis of estimated glomerular filtration rate (eGFR) underlying the plasma creatinine fluctuations after renal transplant. We tried to validate an early parameter of DGF in a renal transplant population based on the kinetic estimation of glomerular filtration rate, since this formula adds a quantitative dimension to the assessment of kidney function, and consequently predicting DGF could get a better post-transplant management.

**Method:** This is a longitudinal study of 886 renal transplant recipients from our center during the first post-transplant month. As we are searching for functional biochemical markers in renal transplant from deceased donors, we excluded patients with primary graft dysfunction. The final simple was composed of 574 adult kidney transplant recipients, 348 renal transplant from donors after circulatory death (DCD) and 226 from donors after brain death (DBD). The following are analyzed S-creatinine concentrations, serum Lactate dehydrogenase (LDH) and urinary creatinine excretion rate (CER).

**Results:** In DCD there was a significant correlation between DGF duration and all KeGFR and CER determinations during the first post-transplant week. The parameters that achieved the best correlation to predict DGF were KeGFR (r = 0.515; p < 0.001) and CER on the fourth day (r = 0.59; p < 0.001). We observed that serum LDH on the first day in the DBD group is associated with worse renal graft function at first, third month and one year after transplantation (p < 0.045, p < 0.05 and p < 0.067 respectively).

**Conclusion:** The determination of KeGFR and CER could predict the duration of DGE especially in DCD recipients. DCD recipients with DGF have significantly better graft survival at one year than DBD recipients with DGF (p < 0.001).

P <.01). 1.b ROC curve of the urinary creatinine excretion rate on day 4 to predict DGF greater than one and two weeks in recipients from renal transplant from donor after circulatory death.(AUC 0.82 p <.01)
HLA COMPATIBILITY DOES NOT INFLUENCE KIDNEY GRAFT SURVIVAL AND DOES NOT IMPACT THE DEVELOPMENT OF POST-TRANSPLANT NEOPLASIA

Giulia Bartoli, Andrea Dello Strologo, Simona Simone, Maria Arena, Maria Paola Salerno, Patrizia Silvestri, Pasquale Ditonno, Jacopo Romagnoli, Loreto Gesualdo and Giuseppe Grandaliano

1 UOC di Nefrologia, Dialisi e Trapianto, Dipartimento di Medicina e Chirurgia Traslazionale, Università Cattolica del Sacro Cuore, Roma, Italy, 2UOC Nefrologia, Dialisi e Trapianto, Policlinico “Consorziale”, Università degli Studi A. Moro, Bari, Bari, Italy, 3UOC di Nefrologia, Dialisi e Trapianto, Roma, Italy, 4UOS Trapianti di Rene’, Fondazione Policlinico Universitario A. Gemelli IRCCS, Roma, Italia, Roma, Italy and 5UOC Urologia, Policlinico “Consorziale”, Università degli Studi A. Moro, Bari, Bari, Italia, Italia, Italy

Background and Aims: HLA compatibility is a key issue in deceased and living kidney allocation, although the continuous improvement of immunosuppressive protocols might have reduced its relevance. However, an increased immunosuppression is associated with several adverse events, including the development of post-transplant neoplasia. Indeed, several reports demonstrated that the improvement in immunosuppressive drug efficiency corresponded to an increase incidence of malignancies after kidney transplantation. Thus, the aim of our study was to investigate the effect of HLA compatibility on kidney graft survival and incidence of post-transplant neoplasia.

Method: This is an observational, retrospective, multicenter center study including 1506 patients receiving a single kidney transplant at the Gemelli and Policlinico “Consorziale” kidney transplant centers from 1/1/2000 to 1/2/2022. The primary outcomes were death-censored graft survival and the development of post-transplant neoplasia. HLA compatibility was measured as the number of HLA mismatches (MM) at the three main class I (A and B) and class II (DR) loci. To this purpose, both donor and recipients were genotyped for HLA A, B and DR. We included in the analysis all deceased and living kidney donor transplants and excluded recipients from ABO incompatible living kidney donors and with pre-transplant donor specific antibodies.

Results: Based on HLA compatibility, we divided our patients’ population in three groups (0-2 MM, 369 patients 3-4 MM, 856 patients and 5-6 MM, 281 patients). At univariate analysis (Kaplan-Meyer) number of MM were not associated with death-censored graft survival and the development of post-transplant neoplasia. HLA compatibility was measured as the number of HLA mismatches (MM) at the three main class I (A and B) and class II (DR) loci. To this purpose, both donor and recipients were genotyped for HLA A, B and DR. We included in the analysis all deceased and living kidney donor transplants and excluded recipients from ABO incompatible living kidney donors and with pre-transplant donor specific antibodies.

Conclusion: In this observational retrospective multicenter analysis, we demonstrated that HLA incompatibility, as indicated by the number of HLA A, B and DR MM, does not predict death-censored graft survival and does not impact the development of post-transplant neoplasia. Our observation would suggest that the missing effect of HLA compatibility on graft outcome is not associated with an increased long-term over-immunosuppression.

CINACALCET IMPACT ON ESTIMATED GLOMERULAR FILTRATION RATE AMONG KIDNEY TRANSPLANT RECIPIENTS WITH SECONDARY HYPERPARATHYROIDISM: A CASE-CONTROL STUDY

Jeremy Han Yee Yu, Thomas Goronfot, Clarisse Kerleau, Magali Giral, Samuel Frey and Lucile Figureau

1 University Hospital of Nantes, Department of Nephrology and Clinical Immunology, Nantes, France, 2University Hospital of Nantes, Data Clinic, Nantes, France, 3University Hospital of Nantes, Center for Research in Transplantation and Translational Immunology, Nantes, France and 4University Hospital of Nantes, Institute for Digestive Tract Diseases, Nantes, France

Background and Aims: Secondary hyperparathyroidism (sHPT) is common in kidney transplant recipients. It remains unknown if Calcimimetic agents (as cinacalcet), oftenly used in this context, have an impact on mortality or morbidity. The objective of this work was to compare the renal and cardiovascular outcome of kidney transplanted patients with sHPT.

Method: Data from January 2008 to December 2019 were retrospectively extracted from the DIVAT database. 575 kidney transplant recipients with sHPT (PTH > 100 pg/ml) followed in Nantes University Hospital were separated into two groups: Treated (cinacalcet) and sHPT Controls (no cinacalcet). A propensity score was used to match the patients (age, sex, first transplant, transplantation before/after 2015, time on dialysis, history of cardiovascular disease, initial condition, anti-HLA class I and II immunization, corticosteroids, serum parathormone level). Biological data (including estimated glomerular filtration rate by CKD-Epi formula), cardiovascular events (coronaropathy, obliterating arteriopathy of the lower limbs, stroke), return in dialysis or related death were extracted from one year of transplantation to the last follow-up. Time-varying exposure Cox PH model was used.

Results: 292 patients were included after matching (146 Treated, 146 sHPT Controls). After one year of transplantation, serum parathormone was significantly higher in Treated patients compared to sHPT Controls (152 pg/mL vs 111 pg/mL respectively, p < 0.001), suggesting a more severe sHPT in Treated patients. 7% of Treated and 10% of sHPT Controls suffered from a cardiovascular event or related death during the follow up (HR = 1.28 [0.52; 3.14], p = 0.6). Return to dialysis or related death were more frequent in the Treated patients (HR: 1.90 [0.97 - 3.75], p = 0.06). At 48 months post-transplantation, estimated glomerular filtration rate was significantly decreased in Treated patients compared to sHPT controls (52.3 mL/min/1.73 m² vs 44.1, p = 0.006).

Conclusion: Our study highlights that kidney transplant recipients with sHPT treated with cinacalcet have a worse kidney graft outcome than non-treated sHPT patients. It remains to be assessed if this reflects an underlying more severe sHPT condition or a direct effect of cinacalcet on the graft function. This study needs to be completed by the assessment of bone mineralization. Parathyroidectomy for sHPT should be discussed in kidney transplant recipients with impaired glomerular filtration rate and/or cardiovascular events.

PROSPECTIVE ASSESSMENT OF THE NEED FOR AND ADDED VALUE OF MOLECULAR DIAGNOSTICS OF KIDNEY ALLOGRAFT BIOPSIES: AN EVALUATION IN CLINICAL PRACTICE

Nicolas Schmid, Lukas Weidmann, Seraina von Moos, Birgit Helmcen, Ariana Gasper, Thomas Mueller and Thomas Schachter

1 University Hospital Zurich, Division of Nephrology, Zurich, Switzerland and 2University Hospital Zurich, Institute of Pathology, Zurich, Switzerland

Background and Aims: The Molecular Microscope Diagnostic System (MMDx) may resolve inconclusive histology findings, as preserved biopsy material can be examined after histology findings have been obtained. The extent to which this proposed approach can be implemented in clinical practice remains an open question.

Method: We prospectively analyzed 104 consecutive indication kidney allograft biopsies by histology and molecular diagnostics at the University Hospital Zurich from April 2022 to December 2022. Pathologists and clinicians with experience in molecular diagnostics assessed the need for MMDx by questionnaire when the histology report was available. Clinicians then assessed the added value of the molecular diagnostics by questionnaire when the MMDx report was available.

Results: 29 of 104 cases (28%) showed rejection by histology, 42 of 104 cases (40%) showed no rejection by histology, and 33 of 104 cases (32%) showed histologic findings insufficient to diagnose ABMR due to an absence of diagnostic criteria groups 2 and/or 3. Pathologists considered molecular diagnostics indicated in 42 of 104 cases (40%), 9 cases to give extra confidence, and 33 cases for diagnostic clarification concerning rejection. Clinicians considered molecular diagnostics indicated in 54 of 104 (52%) cases, 5 cases to give extra confidence, and 49 for diagnostic clarification concerning rejection. In 33 cases with histologic findings insufficient to diagnose ABMR, molecular diagnostics were considered indicated by pathologists and clinicians. Molecular diagnostics allowed the diagnosis of ABMR in 8 of 33 cases (24%). In addition, 11 of 104 cases (11%) showed a discrepancy between the histologic findings and the molecular diagnosis. Clinicians considered adjustment of treatment based on the MMDx report in 3 of 11 discrepant cases. Pathologists and clinicians considered molecular diagnostics indicated in 2 of 11 and 3 of 11 discrepant cases, respectively.

Conclusion: The need for molecular diagnostics goes beyond the recommendation of the 2018 Banff classification for histologic findings insufficient to diagnose ABMR. However, the added value of molecular diagnostics appears to be largely limited to these cases.
Results: A total of 1498 patients underwent renal transplant in this center. Only 33 patients had unusual/rare infections like nocardiosis, Rhodococcus, Melioidosis, Pneumocystis, Aspergillosis, Histoplasmosis, Parvovirus, and Parvovirus. The high index of suspicion should be present when patient is not responding to empirical antibiotics and culture didn’t grow routine organisms. The role of invasive investigations like bronchoscopy with BAL fluid would be considered whenever atypical infections like nocardiosis and aspergillosis were considered. Post-transplant cutaneous abscesses should not be treated with empirical antibiotics and always culture should be done to rule out infections like nocardiosis, pheohyphomycosis and histoplasmosis as treatment is different for each organism. Overall, the high index of suspicion, timely diagnosis, correct drug and duration of treatment will save the graft and patient.
a reduction in 77%, gastrointestinal side effects in 34%, EBV in 19% (two KTRs developed PTLD), CMV in 15%, and BK polyomavirus in 15%. The reduction was significantly more pronounced in KTRs under 11 years (87% vs. 61%, p=0.044). Tacrolimus seemed well tolerated and was sufficiently regulated according to a target through of five microg/L two months after transplantation (Figure 2).

**Conclusion:** Despite 74% of the KTRs receiving reduced immunosuppressive medication according to our protocol, the rejection rate was low, the graft survival was comparable to European reports, and only 11% developed dnDSA during follow-up. Scheduled reduction of MMF shortly after transplantation could decrease the adverse side effects and improve the treatment of paediatric KTRs.

**Background and Aims:** Alterations of bone metabolism are a hallmark of chronic kidney disease (CKD) patients and do not completely ameliorate after kidney transplantation. In the setting of a secondary analysis of a RCT, we evaluated changes of bone turnover biomarkers (BTM) and their associations with changes of bone mineral density (BMD) as assessed by DXA.

**Method:** Sixty-six Kidney Transplant (KTx) recipients were enrolled between 2014-2017. In these patients, at baseline (T0) and 12 months (T12) we measured BTM (Figure 1). The prevalence of vitamin K deficiency was assessed based on undercarboxylated-BGP (uc-BGP) cut-off: > = 4.5 ng/ml, whilst dephosphorylated-ucMGP (dp-ucMGP) we considered a cut-off > 500 pmol/L levels. DXA data were assessed at lumbar spine, femoral neck, total hip, one-third and ultradistal radius both baseline and after one year, evaluating the changes in areal BMD (aBMD). Results were expressed as mean ±SD or median and inter-quartile range, as appropriate. Correlations were investigated by Spearman’s analysis.

**Results:** The mean age of enrolled patients was 51 ± 13 years, 34% were female. BMI was on average 27.8 ± 5.5 kg/m². 24 patients (39.3%) were pre-emptive and 37 (60.7%) on dialysis and 19% of patients had a history of fracture. In Figure 1 the trend of BTM 1 year after KTx. We highlighted a significant reduction of PTH, CTX, P1NP, and VKDPs. This latter while improving but was not completely restored. Table 1 shows the correlations between the percentage variation of BTM and percentage variation of BMD at several sites evaluated.

**Conclusion:** In the first-year post-transplant, along with the improvement of renal function, PTH values were reduced as well those of CTX and P1NP. Moreover, we observed an inverse correlation between BTM and BMD, the reduction of bone turnover expressed by the trend of BTM translates into an improvement of BMD.
**Figure 1:** Significative changes of BTM (A) and VKDPs (B) in first-year post-transplant.

**Table 1: Spearman Correlation between BTM and percentage change of aBMD at 12 moths. Significative correlations are expressed in bold. P values are given when < 0.05.**

**Background and Aims:** Viruses are among the most common causes of opportunistic infection after transplantation and an accurate screening and follow-up is needed in order to prevent related complication as systemic damages and worsening of kidney function. On the other hand, in the first years after transplantation, antibody-mediated rejection (ABMR) is one of the first cause of graft lost and de novo production of donor specific antibody (dnDSAs) is the main source. In this monocentric study we analysed data of 255 patient transplanted from January 2016 to February 2022. We studied the incidence of viral infection and dnDSAs in the first one year after transplantation in different sub-groups of patients.

**Method:** Data was obtained from our monocentric registry, from January 2016 to February 2022. Starting from 299 kidney transplantation we obtained 255 patients with a complete annual follow-up for viral infection and DSA monitoring. We compared the incidence of viral infection and dnDSAs in
Abstracts

IMMUNOLOGIC EFFECTS OF THE DECREASE OF IMMUNOSUPPRESSION AFTER SARS-COV-2 INFECTION IN KIDNEY TRANSPLANT RECIPIENTS

Marina Urrutia, Javier Paúl, Maria Molina Gomez, Josep Riera, Carles Cañameras Fugasot, Ines Perezpaya, Omar Taco, Rosana Gelpi, Angela Casas, Laura Cañas, Rosely Rodriguez, Jordi Bover and Ana Vila

Hospital Universitari Germans Trias i Pujol, Badalona, Spain

Background and Aims: The decrease of immunosuppression (IS) in kidney transplant (KT) recipients with SARS-CoV-2 infection was proposed during the first years of the pandemic due to the lack of knowledge of the course of the infection and the absence of vaccines and specific treatment. The effects of this decrease are being assessed in a medium-long term.

Method: Unicentric retrospective study that included 19 patients with a kidney biopsy after a SARS-CoV-2 infection (120 days). We measured acute kidney injury (AKI) after de infection, decrease in the IS during the infection, rejection episodes and renal function evolution during 24 months after the infection.

Results: The studied group was constituted by 19 patients from which 57.9% (11/19) men, age 56 (51, 70), being the first KT in 78.9% (15/19) of them. The IS induction was in a 57.9% (11/19) Basiliximab and in a 42.1% (8/19) of patients. There was a graft loss in 26.3% (5/19), transplanted treated with rATG as induction therapy (DBDt+DCD). rATG was associated with higher dsDNAs rate, especially in DBD treated with rATG. On the best of our knowledge, this data was never observed before. These data, due to the low number of cases, need to be confirmed from larger cohorts. Moreover our study underlines how significant is to develop a personalized approach in order to reduce complications associated to immunosuppressive therapies.

Conclusion: Viral infection and dsDNAs are two paramount aspects in kidney transplantation and demonstrate different incidences depending on donation profile and immunosuppressive induction therapy. Specifically rATG seems to be associated to an higher rate of viral infection and DCD is the more relevant sub-group. Furthermore, rATG was associated with higher dsDNAs.

Background and Aims: Post-transplantation lymphoproliferative disorder (PTLD) is a potentially fatal complication of transplantation, pathogenesis of which remains to be fully understood. In solid organ transplant recipients, the risk of disease development is associated with graft type and is lowest for kidney (KTR), intermediate for liver (ITR) and high for lung (LngTR) transplant recipients. The aim of this study was to investigate the factors contributing to the development and treatment outcomes of PTLD and compare their impact on the populations of KTRs, ITRs and LngTRs.

Figure 1: Incidence of viral infection and dnDSAs in DBDs, DBDt, DCD and rATG.
Method: In this retrospective cohort study we have included all KTRs, LTRs and LngTRs diagnosed with PTLD at four transplantation centers in Poland between 2002 and 2022. The following data were collected from the patients’ medical records: immunosuppression (IS), viral infections, PTLD type, treatment and outcomes. Mann-Whitney U-test was used to assess the differences in group composition, and univariate Cox regression was used to determine the impact of variables upon PTLD time of onset and patient survival. p-values below 0.05 were considered statistically significant.

Results: We identified 31 KTRs, 31 LTRs and 5 LngTRs who fulfilled the inclusion criteria. Among the patients of the transplantation center leading this study, PTLD was diagnosed in 22 (0.82%) out of 2699 KTRs and 29 (2.03%) out of 1386 LTRs. Two thirds of the patients were male, the median age at first transplantation was 39 years and the median age at PTLD diagnosis was 48 years. KTRs and LTRs significantly differed in IS treatment: more KTRs used steroids (GCS, p = 0.042) and cyclosporin (CsA, p = 0.001), more LTRs used tacrolimus (TAC, p < 0.001) and anti-CD25 induction (p = 0.003). KTRs developed PTLD later than LTRs (141 months after transplantation vs 53 months, p = 0.004) and LngTRs (5 months after transplantation, p = 0.001). Monomorphic PTLD was the most frequent in KTRs (80.6%, p = 0.032). Initial IS treatment reduction was used in 91% of all patients. The groups did not significantly differ in the type of PTLD treatment. TAC had the opposite effect on PTLD time of onset in KTRs (HR = 2.92, 95%CI 1.35-6.34, p = 0.007) and LTRs (HR = 0.18, 95%CI 0.04-0.89, p = 0.036). At the end of the observation period 16.7% of KTRs, 51.6% of LTRs and 80% of LngTRs were alive. Complete remission was achieved in 48.4% of KTRs, 61.3% of LTRs and 80% of LngTRs. KTRs had the highest rate of loss to follow up at 41.4%. Patient survival was longer in patients who were treated with anti-CD20 monotherapy (HR = 0.28, 95%CI 0.08-0.96, p = 0.042) and surgery (HR = 0.33, 95%CI 0.12-0.91, p = 0.031).

Conclusion: KTRs develop PTLD significantly later than LTRs and LngTRs, and disease onset is associated with TAC use. Low KTR survival rate is related to the high rate of loss to follow up (e.g. loss of graft function and return to hemodialysis). Surgical treatment, used mainly in focal PTLD improves patients’ survival. The positive effect of anti-CD20 monotherapy on patients’ survival reflects the efficacy of current stratified treatment regimens for PTLD.

#6603
THE ROLE OF ANTICOAGULATION IN KIDNEY TRANSPLANTATIONS FROM UDCD WITH HIGH RESISTANCE INDEX

Maria Molina Gomez1,2, Marina Urrutia3, Gregorio A. Romero-González1, Javier Paíl3, Fredzia Amada Graterol Torres3, Josep Riera2, Carles Cañameras Fugastos1, Ines Perezpaya2, Omar Tác3, Laura Cañas2, Rosely Rodriguez2, Mario Fernandez1, Ester Gonzalez Montes1, Angel Sevillano1, Enrique Morales1, Jimena Cabrera3, Jordi Bover1, Ana Vila2 and Amado Andrés Belmonte1

1Hospital Universitario 12 de Octubre, Madrid, Spain, 2Hospital Universitari Germans Trias i Pujol, Badalona, Spain and 3Hospital Evangélico y Militar. PPTG Centro de Nefrología Hospital de Clínicas Fac de Medicina UDELAR, Montevideo, Uruguay

Background: Kidney transplantations (KT) from uncontrolled donation after cardiac death (uDCD) achieve very good outcomes to short and long follow-up, but the incidence of primary non-function and venous thrombosis (VT) is very high. The resistance index (RI) after kidney transplantation increases in the VT cases and in other kidney diseases.

Aims: To describe the effect of prophylactic anticoagulation in KT from uDCD with RI ≥0.8 to avoid VT and its secondary effect.

Method: Unicentric retrospective cohorts study that included all KT from uDCD with RI ≥0.8 measured by ecodoppler in the first 72 hours post-transplantation. We compared one group, which never received anticoagulation (Group I), and a second one which received prophylactic anticoagulation (Group II). Sodic heparin was the administer anticoagulant to achieve aPTT 1.5-2 time normal range and/or low molecular weight heparin adjusted to patient’s weight and renal function.

Results: We included 107 KT from uDCD with RI ≥0.8, with 36 in Group I and 76 in Group II. In Group I the donors were younger (39 ± 12 vs 46 ± 8; p = 0.003) and there were more men donors (97.2% vs 81.7%; p = 0.032). The prevalence of VT was higher in Group I (19.4% vs 0%; p = 0.001). Patients in Group II needed more red blood transfusions (19.4% vs 39.4%; p = 0.05) and had more macroscopic haematuria (5.6% vs 21.1%; p = 0.049). The competing risk analysis showed a higher probability to develop a VT in non-anticoagulation group (p = 0.00012) than anticoagulation group or other causes of primary non-function (Figure 1).

Conclusion: The prophylactic anticoagulation treatment in KT from uDCD with RI ≥0.8 decreases the VT incidence and it is safe for a donor recipient.

#6128
IMPACT OF MANNOSE-BINDING LECTIN DEFICIENCY ON GRAFT SURVIVAL IN TRANSPLANT RECIPIENTS WITH IGAN

Emma Stea, Francesco Pesce, Rossana Franzin, Elisabetta Sturdà, Ighli Di Bari, Paola Pontrelli and Loreto Gesualdo

University of Bari Aldo Moro, Bari, Italy, Nephrology, Dialysis and Transplantation Unit, BarI, Italy

Background and Aims: The progression of IgA nephropathy (IgAN) has been associated with Mannose -Binding Lectin levels (both excess or deficiency). The MBL deficiency, is associated with the rs5030737, the rs1800450 and the rs1800451, who represent the “O” allele. Since lectin pathway deregulation may impact on IgA progression on native kidney we hypothesized that the presence of the “O” allele and therefore MBL deficiency, could influence also the graft survival in recipients with a biopsy-proven diagnosis of IgAN on native kidneys. Therefore we investigated the role of MBL “O” allele in kidney transplant recipients with IgAN.

Method: We enrolled 32 kidney transplant recipients with biopsy-proven IgAN on the native kidney. The region in MBL encompassing the SNPs rs5030737, rs1800450 and rs1800451 were amplified using PCR and analyzed by Sanger sequencing.Clinical data at baseline and during the follow-up were collected from patients’ records. An eGFR ≥60mL/min/1.73m2 (MDRD equation) was considered as main outcome at univariate and multivariate analyses.

Results: The 38% of patients carry the “O” allele and 62% of patients the “A” allele which is associated with the wild genotype. No difference between the two groups as for demographic features, donor and transplant-related variables has been found. Interestingly we found that patients with the “O” allele had a worse graft outcome (P = 0.01) during a mean follow-up of 151 months (Figure 1). The “O” allele was an independent predictor for the graft survival in a Cox survival analysis model adjusted for donor’s and recipient’s age, acute rejection,
Figure 1: Impact of the "A" Vs "O" allele on graft outcome, KM survival curve.

Figure 2: Correlation between genotype and MBL serum levels. "A" allele: Median MBL value = 527.05 ng/ml (interquartile 366.7-1788.5 ng/ml); "O" allele: Median MBL value = 229 ng/ml (interquartile 110.42-296.7). P < 0.001.

and disease recurrence (HR 0.046; 95% I.C. 0.005-0.423; P = 0.01). Moreover we found a link between the genetic background and the MBL serum level (Figure 2).

Conclusion: Our study suggest a potential role of the MBL deficiency in the longterm graft dysfunction in kidney transplant recipient with IgAN.

HYPERPARATHYROIDISM DURING 1ST YEAR OF RENAL TRANSPLANT IS ASSOCIATED WITH LONG TERM GRAFT LOSS

Carlo Maria Alfieri1,2, Paolo Molinari1, Elisa Cicero3, Donata Cresseri1, Anna Regalia3, Maria Rosaria Campise1, Simona Verdesca3, Evaldo Favi1,2 and Giuseppe Castellano1,2

1 Fondazione IRCCS Ca Granda Ospedale Maggiore Policlinico, Milan, Italy and 2 University of Milan, Milano, Italy

Background and Aims: Persistent hyperparathyroidism (HPT) is a frequent problem, especially during the first year after Renal transplant (RTx). We aimed to evaluate the possible association between parathormone (PTH) levels during 1st year of RTx and long-term graft loss (GL) in RTx patients (RTx-p).

Method: We retrospectively evaluated 871 RTx-p, transplanted in our unit from 2004 to 2020. We measured main renal function and mineral metabolism parameters at 1 month (T1), 6 months (T6) and 12 months (T12) after RTx. Renal outcome was intended as GL during the global follow-up (FU) of 103 ± 60 mths.

Results: Mean age at RTx was 49±13 yrs and 58% of RTx-p were male. Most of the RTx-p were on hemodialysis (HD) before RTx (77%) with a mean dialysis vintage of 53±52 months. Most of our cohort (84%) received a kidney from a deceased donor. HPT was highly prevalent during the 1st year of FU; at T1 79% of RTx-p were HPT, of which 63% had secondary HPT (SHPT) and 16% had tertiary HPT (THPT). Comparable prevalence was observed at T6 (HPT 80%; SHPT 64%; THPT 16%) and at T12 (HPT 77%; SHPT 62%; THPT 15%). A strong significant correlation was found between HPT type and GL at every time point [T1 GL: no HPT 6%, SHPT 11% THPT 24%, P < 0.0001 - T6 GL: no HPT 9%, SHPT 9% THPT 22%, P < 0.0001 - T12 GL: no HPT 8%, SHPT 9% THPT 21%, P < 0.001]. Moreover, PTH levels at T1 (GL-: 90.3 [50.6-165.6] vs. GL+: 61.7 [37.4-98.8] < 0.0001), at T6 (GL-: 83.6 [47.1-152.4] vs. GL+: 56.1 [38.3-89.7] < 0.0001) and at T12 (GL-: 69.8 [44-121.9] vs. GL+: 54.6 [36.4-84.1] p = 0.008) were significantly correlated to GL. PTH levels at T1 and T6 were associated with long-term GL [T1, OR: 3.3 (1.3-8.1), p = 0.01 - T6, OR: 3.9 (1.7-9.2), p = 0.01]. Then we considered PTH levels as mean exposure during the first year. Mean PTH exposure alone was strongly associated with GL [OR: 5.7 (2.7-11.9), p < 0.0001]. A multivariate logistic regression analysis was also performed. In the model, we considered 1st year mean PTH exposure and the main factors associated with GL (pre-RTx dialysis vintage, 1st year rejection, T12 uric acid, T12-Proteinuria and T12-MDRD). Mean PTH exposure remained strongly and independently associated with long-term GL (OR 3.1 [1.4-7.1], p = 0.008). We finally performed a ROC curve to calculate the best 1st-year mean PTH cut-off to predict long-term GL. AUC was 0.658, with a p < 0.0001. Using Youden index we identified the best mean PTH cut-off to be 88.6 pg/ml.

Conclusion: In our cohort of 871 RTx-p, the prevalence of HPT during the first year of RTx is quite high. High PTH levels during 1st year of RTx were independently associated with long-term GL. HPT might be considered a therapeutic target to prevent long-term graft failure.

#5256

REACTIVATION OF HEPATITIS B VIRUS IN KIDNEY TRANSPLANT RECIPIENTS WITH RESOLVED INFECTION: A SINGLE-CENTER EXPERIENCE

Gonçalo Pimenta, André Weigert and Sara Querido Conde

Centro Hospitalar Lisboa Ocidental, Nephrology, Lisbon, Portugal

Background and Aims: Patients with end-stage renal disease (ESRD) frequently present serologic evidence of previous contact with hepatitis B virus (HBV). Although uncommon, HBV reactivation after kidney transplantation (KT) may cause serious complications and adverse outcomes in these patients. However, data regarding risk factors for reactivation are still scarce. This study aims to describe a cohort of patients with resolved HBV infection who showed reactivation of the virus after KT.

Method: Retrospective cohort study including patients with resolved HBV infection who underwent KT between August 2007 and December 2021. Resolved HBV infection was defined as being seronegative to HB surface
antigen (HBsAg) and seropositive to HB core antibody (HBcAb), regardless of HB surface antibody (HBeAb) status. HBV reactivation after KT was defined as seropositivity to HBsAg or presence of HBV-DNA in the serum (viremia). Preemptive prophylactic entecavir was not used. Demographic and clinical data were collected from the electronic records.

**Results:** A total of 104 patients (70.2% male) were included with a mean age of 52±10 years. Prior to KT, 93.3% were seropositive to HBsAb. Seropositivity to other viruses was present in 18 patients: human immunodeficiency virus (HIV) alone in 5 patients; hepatitis C virus (HCV) alone in 11 patients; and coinfection in 2 patients. Deceased-donor KT was performed in 94.2% and only 9 patients had a previous KT. Rituximab was used as induction immunosuppressive therapy in 13 patients. Median follow-up time after KT was 75 months (IQR 37-115). HBV reactivation occurred in 6 patients with a median time after KT of 5 months (IQR 3-11.5). At reactivation diagnosis, median HBsAg titer was 83.2 (IQR 34-784.5; reference range < 1) and median viral load was 6.7 × 10^6 copies/mL (IQR 0.4 × 10^6-378 × 10^6). Only one patient presented seropositivity to HBsAg without viremia. Half of these patients were seropositive to HBsAb prior to KT and became seronegative at reactivation diagnosis. No liver enzyme elevation was registered at reactivation diagnosis. Donor HBcAb status, coinfection with HIV or HCV, and recipient HBsAb status were not associated to HBV reactivation after diagnosis. Donor HBcAb status, coinfection with HIV or HCV, and recipient HBsAb status were not associated to HBV reactivation after diagnosis. Half of these patients were seropositive to HBsAb prior to KT and became seronegative at reactivation diagnosis. No liver enzyme elevation was registered at reactivation diagnosis. Donor HBcAb status, coinfection with HIV or HCV, and recipient HBsAb status were not associated to HBV reactivation after diagnosis. Half of these patients were seropositive to HBsAb prior to KT and became seronegative at reactivation diagnosis. No liver enzyme elevation was registered at reactivation diagnosis.

**Conclusion:** Hepatitis B virus reactivation is possible after kidney transplantation and may pose major adjustments to the treatment, namely the immunosuppressive therapy. Careful monitoring of hepatitis B virus serology and viremia could be particularly useful in early diagnosis and prompt approach to its reactivation. Larger and multi-center studies are warranted to identify specific risk factors in this population and prevent reactivation.

**DIAGNOSTIC YIELD AND CLINICAL SIGNIFICANCE OF SYSTEMATIC CARDIAC SCREENING OF KIDNEY TRANSPLANT CANDIDATES USING CARDIAC COMPUTED TOMOGRAPHY**

Marie Bodilsen Nielsen1,2, Malene Iversen1, Amal Derali1, Jonathan Dahl1, Bente Jespersen1, Per Iversen1, Simon Winther1 and Henrik Birn1,2

1 Aarhus University Hospital, Department of Renal Medicine, Aarhus N, Denmark; 2 Aarhus University, Department of Biomedicine, Aarhus C, Denmark; 3 Gødstrup Hospital, Department of Cardiology, Herning, Denmark and 4 Aarhus University, Department of Clinical Medicine, Aarhus, Denmark

**Background and Aims:** Cardiovascular screening of kidney transplant candidates is currently recommended, although the patient value is presently questioned. The prognostic ability is known, whereas systematic screening may have less recognized effects such as incidental findings, triggering of additional investigations, procedural complications, delay of transplantation and deselection of patients for kidney transplantation. To address this, we characterized the diagnostic yield and clinical implications of systematic screening for cardiovascular disease using cardiac computed tomography (CT) in asymptomatic kidney transplant candidates.

**Method:** In a single-centre, observational study, we included all potential kidney transplant candidates ≥ 40 years or with diabetes or on dialysis treatment ≥ 5 years, who were systematically referred to cardiac CT (a non-contrast enhanced CT scan and a coronary CT angiography) prior to kidney transplantation between March 2014 and September 2019 in North and Central Denmark Regions. Patient records were examined to obtain data on baseline characteristics, additional investigations, incidental findings, conference decisions.

**Results:** In total, 473 patients underwent cardiac CT. The screening programme led to additional cardiac investigations in 155 patients (33%) and viremia could be particularly useful in early diagnosis and prompt approach to its reactivation. Larger and multi-center studies are warranted to identify specific risk factors in this population and prevent reactivation.

**Conclusion:** The clinical significance of the screening by cardiac CT was limited, and one third of patients had to go through additional investigations. Few patients were revascularised and no patients rejected for transplantation. No evidence of contrast-induced acceleration of kidney function decline was observed.

**OMNIGRAF (COMBINED GENE EXPRESSION AND DD-CF DNA) USE IN MONITORING RENAL ALLOGRAFT REJECTION IN MULTIORGAN TRANSPLANT RECIPIENTS**

Ziad Zaky1, James Fleming2 and Juston Weems2

1 Cleveland Clinic, Glickman Urological and Kidney Institute, Cleveland, United States of America and 2 Eurofins, Transplant Genomics, Framingham, MA, United States of America

**Background and Aims:** To date there is no clinically available non-invasive biomarker to monitor for renal allograft rejection in multiorgan transplant recipients. TruGraf (Gene expression profile) and TRAC (dd-cf DNA), as part of the biomarker panel OmniGraf, have shown to be reliable “rule out” tests for subclinical rejection in stable kidney transplant recipients. However, the validity and utility of these tests in monitoring for renal allograft rejections in the setting of multiorgan transplants has yet to be assessed. The aim of this study is to assess the feasibility of using the biomarkers individually, as well as together in the OmniGraf biomarker panel, to assist in making the decision to perform a renal allograft biopsy in multiorgan transplant recipients.

**Method:** This is an ongoing prospective, observational sample collection study in any multiorgan (kidney + non-renal organ) undergoing a renal allograft biopsy. Biopsies were considered positive if they showed rejection in the kidney based on Banff 2019 and included borderline changes as positive results. Copper-Pearson 95% CI were used for sensitivity, specificity, and accuracy; standard logit CIs were used for NPV and PPV. For TruGraf, (TX = negative result) and (not-TX = positive test). For TRAC, 0.7% was used as the threshold for all organs except for those that had a liver transplant, where a threshold of 15% was used to determine positive vs. negative.

**Results:** Paired renal allograft surveillance biopsies and biomarker samples were available for 20 patients. Of the 20, 9 (45%) were liver-kidney transplants, 6 (30%) were heart-kidney transplants, and 5 (25%) were kidney-pancreas transplants. Nine (45%) of the patients were male, 14 (70%) were White, 5 years, who were systematically referred to cardiac CT (a non-contrast enhanced CT scan and a coronary CT angiography) prior to kidney transplantation between March 2014 and September 2019 in North and Central Denmark Regions. Patient records were examined to obtain data on baseline characteristics, additional investigations, incidental findings, conference decisions.

**Results:** In total, 473 patients underwent cardiac CT. The screening programme led to additional cardiac investigations in 155 patients (33%) and viremia could be particularly useful in early diagnosis and prompt approach to its reactivation. Larger and multi-center studies are warranted to identify specific risk factors in this population and prevent reactivation.

**Conclusion:** The clinical significance of the screening by cardiac CT was limited, and one third of patients had to go through additional investigations. Few patients were revascularised and no patients rejected for transplantation. No evidence of contrast-induced acceleration of kidney function decline was observed.

</tr>
</tbody>
</table>

*OmniGraf -/ used for negative tests, any panel with at least one positive test considered positive.
5 (25%) were Black, and 1 patient was Hispanic. The mean age was 50 ± 13 years. Average SrCr was 1.3 ± 0.5 mg/dL. Of the 20 paired biopsies and samples, 2 (10%) had only TruGraf results, while the other 18 (90%) had OmniGraf (TruGraf and TRAC). There were 2 rejections (borderline changes). Diagnostic performance is presented in tables 1–4. Both TruGraf and TRAC individually had NPV of 89% and 85%, respectively, and PPV of 65% and 73%, respectively. When analyzing the performance of the OmniGraf biomarker panel, OmniGraf +/- showed a 100% PPV and OmniGraf -/+ showed a 100% NPV.

Conclusion: In this analysis of renal allograft biopsies in a multiorgan transplant cohort, TruGraf, TRAC (when using organ-dependent thresholds) had reasonable diagnostic performance as a “rule out” test. When the tests are combined into OmniGraf, the PPV and NPV were 100% when both tests agreed with each other. These outcomes justify potential use and the need for continued analysis of the utility of the OmniGraf biomarker panel in monitoring renal allograft in multiorgan transplant recipients.

HISTOLOGICAL FINDINGS OF ACUTE HUMORAL REJECTION IN PATIENTS WITH STANDARD IMMUNOLOGICAL RISK: ANTIDV-MEDIATED DAMAGE OR MICROVASCULAR INJURY?
Eva Gavela, Julia Kanter, Emma Calatayud Aristoy, Ana Ávila, Cristina Castro Alonso and Maria Asuncion Sancho Calabuig
Hospital Dr Peset, Nephrology, Valencia, Spain

Background and Aims: The development of acute humoral rejection (AHR) is increased in patients with high immunological risk. Taking into account the highly sensitivity from the techniques used to determine anti-HLA antibodies, the histological findings of AHR in the immediate post-transplantation period in patients without preformed anti-HLA antibodies (standard immunological risk) is unexpected. We propose the implication of non-immunological factors as the origin of these findings. Our aim was to evaluate the histological findings of AHR in the immediate post-transplantation period in patients with standard immunological risk and to analyze factors related to its appearance.

Method: A multicenter retrospective study was carried out including renal transplants performed between January-2014 and December-2022, excluding patients with pre-transplant HLA sensitization and failures due to thrombosis. A descriptive analysis of transplant recipients with standard immunological risk who developed histological findings of AHR was made (AHR). In addition, we performed a comparative analysis of this group with the patients who developed AHR with pre-transplant HLA sensitization (AHRs).

Results: Of the 351 patients, 18 (5.1%) presented AHR, all were first transplants without pre-transplant anti-HLA antibodies. Fourteen donors were brain death and four due to controlled circulatory arrest. Banff AHR was grade I in 1 patient, grade II in 13 patients, and III in 3 cases. 50% showed thrombotic microangiopathy (TMA). Seven (38.9%) failed after a mean follow-up of 28.7±26.1 months. The failure etiologies were chronic rejection (3) and primary dysfunction (4). No patient presented anti-HLA antibodies during the follow-up and 3 have received a second transplant without complications. When comparing the AHR group with the AHRs (n = 14), we observed a greater age of the donor in AHR (median 71.5 vs 56.5, p = 0.02) a higher percentage of donor due to controlled circulatory arrest (22% vs 0%, p = 0.005) and with history of Hypertension (66.7% vs 42.9%, p = 0.09). Recipient age was higher in AHRs (median 64.5 vs 51, p = 0.025), with a higher proportion of retransplant in AHRs (42.9% vs 0, p = 0.002). In AHRs, DGF (100% vs 57.1%, p = 0.002) and thrombotic microangiopathy (50% vs 14.3%, p = 0.03) were more frequent. Renal function was worse during the follow-up in AHR (p = 0.05).

Conclusion: The histological finding of RAH in patients with standard immunological risk appears as an aggressive process with negative consequences on graft survival. The absence of anti-HLA antibodies in subsequent follow-up suggests the involvement of non-immunological factors in its developing. Processes related to the maintenance and/or extraction of organs could favor the appearance of microvascular damage, with histological findings suggestive of AHR especially in older grafts and with comorbidity. Studying these cases is essential to identify risk groups and establish appropriate therapeutic strategies.

PREGNANCY OUTCOME AFTER KIDNEY TRANSPLANTATION AND IMPACT ON GRAFT FUNCTION
Ahmed Alkot, Samir Sally, Mohamed Sakhr, Mahmoud Zahrans and Salwa ElWasif
Egypt

Background and Aims: Within 2 to 3 weeks of a successful renal transplantation, the fertility of women in childbearing age improves; however, pregnancy after kidney transplantation is challenging and may be associated with increased maternal and fetal complications. To study the prevalence of pregnancy and pregnancy related complication after kidney transplantation. Method: A retrospective cohort study conducted on 236 patients out of 3000 kidney transplant recipient who underwent renal transplantation (RT) at Mansoura Urology and Nephrology Centre between March 1976 and December 2019, divided into two groups, group I: 118 kidney transplant recipient who experienced pregnancy at any time after kidney transplantation and Group II: 118 kidney allograft recipients who didn’t experience pregnancy after renal transplantation, they were matched according to age, duration of renal transplantation and they are comparable in primary immunosuppressant drugs. All kidney recipients were reviewed for preoperative, operative, and post-operative details also we record maternal and fetal complication.
Results: Prevalence of pregnancy in our centre is 191 pregnancies in 118 women who had undergone kidney transplantation between 1976 and 2019. We have found that the mean age of pregnancy between (26.27±4.37 - 29.89±4.6), the mean gestational age between (33.69±6.4 - 33.7±7.5) weeks, the live birth rate is 126 (66%). Preterm delivery rate in our study is 85 (44.5%), neonatal death 8 (4.1%), miscarriage 59 (30.9%), intrauterine foetal death 6 (3.1%) and birth defect 4 (2%). The prevalence rates of gestational hypertension is 87 (45.5%), preeclampsia 48 (25.1%), gestational diabetes 19 (9.9%), urinary tract infection 36 (18.8%), and graft rejection 8 (4.1%) during pregnancy. caesarean section is the most common method of delivery in our study 133 (69.6%). Conclusion: The risk of maternal and fetal complications is still high in RT patients and requires multidisciplinary care. All should be considered in patient counseling and clinical decision making. So we recommend educating the transplanted patients to allow for outcome optimization and minimization of complications.

#5548
THE PROGNOSTIC VALUE OF LYMPHOCYTE SUBSETS IN ANTIBODY RESPONSE AFTER SARS-COV2 VACCINATION IN DIALYSIS PATIENTS AND KIDNEY TRANSPLANT RECIPIENTS
Ioannis Mallioras1, Christos Georgopoulos1, Anila Duni2, Georgios Markopoulos3, Ethlymios Pappas2, Gerasimos Baxevanos2, Konstantina Gartzonika4, Eirini Christaki5, Haralampos Milionis6 and Evangelia Nounoumi1
1University Hospital of Ioannina, Department of Nephrology, Ioannina, Greece, 2University Hospital of Ioannina, Laboratory of Haematology - Unit of Molecular Biology, Ioannina, Greece, 3General Hospital of Filipotes, Hemodialysis Unit, Filipotes, Greece, 4Hatzikosta General Hospital of Ioannina, Internal Medicine Department, Ioannina, Greece, 5University Hospital of Ioannina, Microbiology Laboratory, Ioannina, Greece and 6University Hospital of Ioannina, Department of Internal Medicine, Ioannina, Greece

Background and Aims: Mortality due to SARS-COV-2 infection in hemodialysis (HD) patients and kidney transplant recipients (KTRs) is high. Despite intensive vaccination programs in these vulnerable populations, the adequacy of the respective generated immune responses is significantly lower than the general population and additional booster doses have been recommended by multiple health systems and the World Health Organization. The humoral and cellular immune responses to SARS-COV-2 vaccination remain still under further study in HD patients and KTRs. The aim of our study was to determine the predictive value of lymphocyte subpopulations in the production of antibodies against SARS-CoV-2 after the second dose of the vaccine.

Method: The cohort of this prospective study (ClinicalTrials.gov, NCT04932876) included 34 HD patients and 54 KTRs who received two doses of the BNT162b2 (Pfizer–BioNTech). Lymphocyte subpopulations, including B cells, CD4+ and CD8+ T cells as well as naive and memory T lymphocytes subpopulations among others were analyzed by flow cytometry at three time points, before vaccination (T0), before the 2nd dose (T1), 2 weeks after the 2nd dose (T2). Exclusion criteria included previous infection by SARS-CoV2 as well as infection by SARS-CoV2 during study follow-up. The anti-SARS-CoV2 antibody (Ab) response was assessed by using the ARCHITECT IgG II Quant test (Abbott). Titers >50 arbitrary units (AU)/ml were considered positive for seroconversion at T1 and at T2. A multiple linear regression model was applied separately to the two subgroups of patients.

Results: The mean age of the kidney transplanted recipients was 58.5 years of age while the mean age of HD patients was 68.5 years of age. The analysis of KTRs revealed that the populations of CD19+ lymphocytes, CD3+CD16+56+ cells and CD4+CD45RO lymphocytes can predict antibody formation (p-ANOVA <0.001) based on the multiple regression model. Ab = 4669+519*CD19-226*CD3+CD16+56-139* CD4+CD45RO. The analysis of HD patients revealed that the populations
of CD19+ lymphocytes, CD45RA+CD45RO lymphocytes, CD4 to CD8 ratio, CD3-CD16+56+ cells and CD4+CD45RO lymphocytes can predict antibody formation (p-ANOVA<0.001) based on the multiple regression model: Ab = 20267+835.3*CD19-286*CD45RA+375.2*CD4+ CD45RO+851*CD4/CD8-187.3*CD3-CD16+56+. The two regression models explain the variation of the dependent variable (Ab), according to the adjusted R² index, at a rate of 24% and 67% respectively. The 2 models were analyzed for possible residual autocorrelation (DW statistic > DU > DL in both models). No multicollinearity was observed (All VIF< 1). Normality of the residuals and homoscedasticity also met the criteria for both regression models.

Conclusion: Quantification of lymphocyte subpopulations by flow cytometry appears to have a significant prognostic value regarding development of antibodies after vaccination against SARS-CoV-2, especially in KTRs. The above models can predict patients’ response to vaccination based on specific lymphocyte subpopulations. More studies are needed to validate these predictive models.

#2566
THE EFFECT OF ULTRASOUND-GUIDED COMPRESSION IMMEDIATELY AFTER RENAL GRAFT BIOPSY ON POST BIOPSY BLEEDING
Moataz Fathy Abdelnaceem
Faculty of Medicine Cairo University, Nephrology, Cairo, Egypt

Background and Aims: Renal biopsy is the gold standard for pathological diagnosis of graft dysfunction. Minor complications occur as haematuria, arteriovenous fistula (AVF) and/or small hematomas in 17% of cases. Major complications that require additional treatment as blood transfusion, surgical or interventional procedure. Bleeding may be excessive that may deteriorate ending in graft nephrectomy.

Method: For 6 months period, 213 renal biopsy procedure in clinically indicated patients, performed at interventional nephrology unit 144 men and 59 women, mean age 42 years old, were included. Adequate biopsies were considered showing at least ten glomeruli and 2 blood vessels. Immediate after core withdrawal, operator started ultrasound guided compression using 3.5-5 MHZ convex probe for 5 minutes at site of needle entrance compressing biopsy track against the graft. Post biopsy bleeding examined (peri-nephric, sub-capsular, haematuria and urinary bladder hematomas).

Results: Percentage of bleeding complications was compared with bleeding complications of previous 200 biopsies performed at the same centre with same operator using ordinary hand compression technique. Bleeding complications reduction by more than 60% especially percentage of perinephric hematomas.

Conclusion: Ultrasound guided compression technique post renal graft biopsy may reduce incidence of bleeding complications post biopsy.

POLYOMAVIRUS INFECTION MONITORING BY QUANTITATIVE PCR IN KIDNEY RECIPIENTS AS AN INSTRUMENT FOR PREVENTING POSTTRANSPLANT COMPLICATIONS
Alexandra Arinovich1, Tamara Amrivosieva1, Zoya Bohush1, Natalia Paklonskaya1, Elena Kishkurno1, Kirill Komissarov2 and Aleh Kalachyk3
1 The Republican Research and Practical Center for Epidemiology and Microbiology, The laboratory for infections with a natural reservoir, Minsk, Belarus; 2 State Institution “Minsk Scientific and Practical Center for Surgery, Transplantology and Hematology”, Department of Nephrology, Renal Replacement Therapy and Kidney Transplantation, Minsk, Belarus and 3 State Institution “Minsk Scientific and Practical Center for Surgery, Transplantology and Hematology”, Minsk, Belarus

Background and Aims: Polyomaviruses (PyV) are ubiquitous human viral pathogens. BKV and JCV representing this viral family are common causative agents of viral complications among kidney recipients. Viral load higher than 1 × 10^5 copies/ml in urine (viremia) or 1 × 10^6 copies/ml in serum (viremia) in posttransplantation period may lead to polyomavirus-associated nephropathy (PVAN), hemorrhagic cystitis (HC) or even kidney transplant failure. The aim of the study was to assess PyV reactivation frequency in patients during 12 months after renal transplantation (RT) and to identify molecular subtypes of BKV and JCV.

Method: We examined 3207 samples of biological material (serum and urine) of 763 adult (>18 years) patients who underwent renal transplantation (RT) at the State Institution “Minsk Scientific and Practical Center for Surgery, Transplantology and Hematology”, Healthcare institutions “Brest Regional Clinical Hospital”, “Vitebsk Regional Clinical Hospital Belarus”, “Mogilev Regional Clinical Hospital Belarus”. These patients were divided into 2 groups: group 1 included 394 patients examined only for BKV infection, group 2 – 356 recipients examined for both BKV and JCV infection. Serum and urine samples for regular monitoring were collected from patients before RT, every 2 weeks first 3 months, then at 6, 9, 12 months after RT. In the case of complication development samples from patients were collected later than 1-year monitoring period. PyV DNA was detected by real-time PCR. Viral DNAs from 17 BKV-positive and 11 JCV-positive patients were molecular typed by partial sequencing of VP1 genome region. Confidence intervals for the proportions were calculated using Wald’s method.

Results: Results showed that BKV detection total frequency in the group 1 was 14.47% [11.32%; 18.3%], almost all patients developed viremia, only 2.54% [1.32%; 4.67%] had viremia. In the group 2 PyV DNA was detected in 46.07% [40.96%; 51.26%] of recipients: 19.10% [15.34%; 23.52%] had BKV infection, 19.94% [16.11%; 24.42%] – JCV, 7.02% [4.76%; 10.2%] – BKV+JCV mixed infection. Frequency of viremia was 6.74% [4.53%; 9.87%] in this group. Maximal BKV viral load levels reached 1.2 × 10^12 copies/ml in urine and 5.9 × 10^9 copies/ml in serum. JCV loads were up to 3 × 10^6 copies/ml in urine and 1.2 × 10^8 copies/ml in serum. Then we analyzed frequency of PyV detection before RT and during the first year after RT among the 102 recipients. Results displayed on the Fig. 1 showed that the peak of PyV infection registration and the higher risk for patient had a place on the 1.5-2.5 months after RT. Quantitative monitoring of viral load in posttransplant period was the
basis for the correction of the applied immunosuppressive therapy regimens in relation to the recipients with a high viral load (higher than $1 \times 10^7$ copies/ml in urine or $1 \times 10^4$ copies/ml in serum). The results of molecular typing showed that 17 BKV isolates belonged to subgroups Ib-2 and Iv-c-2 (12 and 5 isolates, respectively). Within subgroups Ib-2 isolates formed 3 clusters corresponding to 3 separate genovariants. JCV isolates belonged to subtype 1A, 1B and 2A (7, 3 and 1 of isolates, respectively). The last one had 99% nucleotide sequence similarity with Greece and South Korea isolates.

**Conclusion:**
Our data demonstrated an importance of PyV DNA monitoring of kidney recipients in the posttransplant period starting from the first days after RT to predict development of PyV complications as PVAN, HC or others by correcting the immunosuppressive therapy.

**OBSERVATIONAL STUDY OF HUMORAL RESPONSE TO SARS-COV-2 MRNA VACCINATION IN A COHORT OF RENAL TRANSPLANTS COMPARED TO PRIMARY IMMUNE DEFICIENCY**

Rahima Hashemi1, Kunigal Shivakumar2, Claire Nicholas3, Malini Bhole4 and Caroline Webber4

1The Dudley Group NHS Foundation Trust, Nephrology, Dudley, United Kingdom, 2The Dudley Group NHS Foundation Trust, Nephrology, United Kingdom, 3Dudley Group NHS Foundation Trust, Nephrology, United Kingdom, 4The Dudley Group NHS Foundation Trust, Immunology, United Kingdom and 5Dudley Group NHS Foundation Trust, Immunology, United Kingdom

**Background and Aims:**
Uraemia in chronic kidney disease impairs both innate and adaptive immune response and is responsible for high failure of vaccination against infection [1]. With a rising global burden of CKD prevalence and mortality, [2] optimising humoral response is important part of management especially in the presence of immunosuppressants in renal transplant patients. There is lacking data in this group and immunosuppressants likely play a bigger role in impairing humoral response hence we compare a group of renal transplant patients (RTs) with a group of patients with primary immunodeficiency (PID).

**Method:**
Non-randomised RTs were recruited between January 2021 to January 2022 and underwent voluntary SARS-CoV-2 vaccination and were tested for immune response. Abbott UK SARS-CoV-2 antibody test was used to identify previous SARS-CoV-2 infection with positive 'N-antibody' titre and immunity with positive 'S-antibody' titre prior to vaccination and 3-8 weeks after each vaccination. Results were analysed with Odds Ratios and Fisher Exact Probability.

**Results:**
A total of 30/51 in the RT group were 'S-antibody' positive; 3 after first vaccination, 21 after second and additional 3 after third vaccination dose (3 patients were 'S-antibody' positive prior to vaccination from previous SARS-CoV-2 infection). In the PID group, 24/30 achieved a significantly positive 'S-antibody' after single vaccination and 27/30 after the second vaccination (Figure 1). No patient tested negative for 'S-antibody' on subsequent testing once they became positive. Compared to PID, transplant patients were much less likely to have positive 'S-antibody' after first vaccination (OR 0.03; 95% CI 0.01 – 0.11, $p < 0.0001$) and second vaccination (OR 0.13; 95% CI 0.03 – 0.46, $p = 0.0012$). Within the transplant group, patients on mycophenolate mofetil (MMF) were less likely (OR 0.12; 95% CI 0.01 – 1.01, $p = 0.036$) to respond to vaccination (Figure 2). Conversely, the patients on azathioprine were more likely to have positive 'S-antibody' response (OR 7.27; 95% CI 0.83 – 63.4). Comparatively patients on tacrolimus were relatively less likely to respond (OR 0.35; 95% CI 0.06 – 1.86). There was no significant difference observed between patients on steroids (OR 0.82 95% CI 0.21 – 3.28), Ciclosporin (OR 1.9; 95% CI 0.33 – 10.88) or patients on two compared to three immunosuppressants (OR 1.6; 95% CI 0.45 – 5.63). Patients within the transplant group who only had single vaccination were less likely to be 'S-antibody' positive (OR 0.21; 95% CI 0.04 – 1.2). There were no significant differences within gender, age, ethnicity, primary renal pathology or co-morbidities.
Conclusion: Renal transplant patients, in particular those on MMF have impaired humoral response to SARS-CoV-2 vaccination compared to PID group which is similar to previous studies [3]. There is significant humoral response to second SARS-CoV-2 vaccination in renal transplant patients which was maintained for the observed study period.

PREVALENCE OF POLYPHARMACY AND ASSOCIATED ADVERSE OUTCOMES IN KIDNEY TRANSPLANT RECIPIENTS

Sungeyeon Kim, Myung-Gyu Kim and Tai Yeon Koo

Department of Internal Medicine, Korea University Anam Hospital, Seoul, Rep. of South Korea

Background and Aims: Polyparmacy (PP) continues to increase, and is associated with numerous adverse clinical outcomes and mortality. Although the burden of medication in kidney transplant recipients (KTRs) is well-known, PP has not been characterized in detail in the KTRs. The aim of this study was to assess the prevalence of PP among KTRs and the association between PP and clinical outcomes in the KTRs.

Method: A total of 1,080 KTRs from multicenter observational cohort study in Korea between 2012 and 2016 (KNOW-KT) were included in the study. PP was defined as the use of more than 10 medications per day.

Results: The PP prevalence at 1, 2, 3, 5, and 8 years after transplantation was 37.9%, 37.3%, 36.5%, 37.1% and 25.4%, respectively. The prevalence of diabetes, dyslipidemia and history of cardiovascular disease was significantly higher in PP group than in non-PP group (the use of fewer than 10 medications). The mean follow-up period was 6.9 years, and there were 69 graft failures, 63 new-onset cardiovascular diseases, and 36 deaths. When the effect of PP prescribed at 1-year post-transplant on clinical outcomes was analyzed, there was no difference in glomerular filtration rate between the non-PP and PP groups, and the hazard ratio of graft failure and death in the PP group was 1.07 (0.718 to 1.59) and 1.37 (0.71 to 2.64), respectively, compared to the non-PP group. However, multivariate analysis adjusted for classical risk factors showed that PP independently increased the risk of new cardiovascular disease (adjusted HR 1.78 (1.07-2.96)) after KT.

Conclusion: These results showed that PP is common in KTRs, and considering the adverse effects of PP on KT outcomes, physician’s attention and efforts are needed to systematically manage and prevent inappropriate PP after KT. Long-term and large-scale research is needed to establish management guidelines for PP in the future.

A STUDY OF CLINICAL SPECTRUM AND THE OUTCOME IN LIVE KIDNEY TRANSPLANT RECIPIENTS IN A TERTIARY CARE CENTRE OF INDIA

Manjuri Sharma, Suresh Singh, Prodip Kumar Doley and Gayatri Pegu

Department of Nephrology, Gauhati Medical College, Guwahati, India

Background and Aims: Kidney transplantation has become the treatment of choice for end-stage renal disease as it leads to longer survival and superior quality of life. There is a remarkable disparity in the access and outcome of kidney transplant across the world. Limited health care resources, difficulty in access or sometimes non availability of appropriate medications, difficulties with transportation, limited availability of Nephrologists are common challenges in developing countries and also within a country like India due to diverse socioeconomic and cultural backgrounds. We present the pattern of infection, various causative organisms, causes of allograft dysfunction and the clinical outcome of the admitted live kidney transplant recipients in Nephrology department of a tertiary care center from North-East India.

Method: This was a single center retrospective observational study carried out in Nephrology Department of Gauhati Medical College, Guwahati, India. The data were collected from the medical records. All the admissions of live renal allograft recipients during the period May 2017- May 2022, were included in the study.

Results: Out of a total of 156 admissions of renal transplant recipients, male to female ratio was 3:7:1. Among the live KTRs basic disease, most common was chronic glomerulonephritis (44.8%) followed by CTID (23.9%). Infection related complications were present in 72 (46.1%) cases. Among infection UTI (n = 29, 16.6%) was most common followed by pneumonia (n = 24, 15.4%)

Various causes of graft dysfunction (biopsy proven) were ATI (Acute tubular injury), CNI toxicity, chronic ABMR, acute TCMR and chronic TCMR. NODAT was found in 14 (9%) of the cases. Out of theses 4 cases, 1 had bacterial pneumonia and 3 had UTI. Of 72 admissions with infection, total 8 patients succumbed to their illness with mortality rate of 11.1%. The most common cause of mortality was sepsis due to UTI.

Conclusion: The number of admissions of renal transplant cases has increased significantly in last 5 years, indicating the increased availability and affordability of renal transplantation in our country. Of 156 admitted live KTRs, infection was seen in 46.1% (n = 72) cases. UTI remained the most common infection (n = 29, 16.6%) followed by pneumonia (n = 24, 15.4%). Graft dysfunction was seen in 33.9% (n = 53) cases. Chronic ABMR was the most common cause (n = 30, 19.2%) for graft dysfunction. Neglect of necessary hygiene, ignorance of regular follow up and dysregulated immunosuppressive doses have contributed to high infection rate. Lack of regular follow up in post-transplant period due to logistic issues and lack of access to immunosuppressive drugs, etc. are major contributing factors for graft dysfunction in our set up. The condition worsens with the difficult terrain, repeated floods, and lack of transportation from remote areas in North Eastern part of India.

EFFECTIVENESS OF ORAL FOSFOMYCIN PROPHYLAXIS IN KIDNEY TRANSPLANT RECIPIENTS

Nancy Daniela Valencia Morales, Isabel Pérez-Flores, Rómulo Katsu Loaya López, María Angeles Moreno de la Higuerá Díaz, Beatriz Rodríguez Cubillo, Natividad Calvo Romero and Ana Sanchez Fructuoso

Hospital Clínico San Carlos, Nefrology, Madrid, Spain

Background and Aims: Urinary tract infections (UTIs) are one of the most common infectious complications in kidney transplant recipients (KTR), which are of great importance due to their high morbidity and recurrent nature. Our main objective was to evaluate the effectiveness of oral fosfomycin prophylaxis in a group of high-risk patients with recurrent/relapsing urinary tract infections.

Method: Retrospective study of a cohort of 60 KTR with frequent UTIs who had been prescribed daily fosfomycin calcium or fosfomycin trometamol every 7-10 days for prophylactic purposes. Demographic, clinical, analytical and microbiological data were collected during a year before and after prophylaxis.

Results: The median age was 61.8 (55.6-71.2) years, 68.3% were men, with 7.4 (2.8-13.6) years since the transplant. The main etiologies of the underlying renal disease were: autosomal dominant polycystic kidney disease 20%, chronic glomerulonephritis 18.3%, chronic tubulointerstitial nephropathy 10%, and diabetic kidney disease 10%. In 51.7% there was chronic pathology of the urinary tract (mainly vesico-prostatic disease, 24.8% and vesico-ureteral reflux, 15%), with a history of urological surgery in 23.3%. Up to 20% of the KTR had some type of endourological device (permanent/intermittent bladder catheter, percutaneous nephrostomy, Bricker, etc.). The most frequently isolated germs were: E. coli and K. pneumoniae, 35.2 and 13.6% pre-prophylaxis and 28.3 and 22.6%, post-prophylaxis, respectively. The median number of UTI pre vs post-prophylaxis was 2 (1-4.75) vs. 1 (0.5-1.6) episode/patient/year (p = 0.001), with a reduction in UTI episodes in 69% of patients. Admissions were also reduced, going from 35% in the pre-prophylaxis year to 10% post (p = 0.001). After prophylaxis, the percentage of resistance to fosfomycin increased from 26 to 54%, and a greater number of multi-resistant germs were isolated, 17.7 pre vs 35% post-. The renal function remained stable during follow-up [CKD-EPI pre - 47.2(20.8) vs 47.2(21.2) ml/min post-].

Conclusion: Oral fosfomycin prophylaxis may be useful in KTR despite the underlying urological pathology, managing to reduce UTI episodes and the need for admission for this reason.
Assessment of Fracture Risk in Kidney Transplant Recipients by FRAX Score Without Bone Mineral Density

Magdy Elsharkawy, Ahmed Emara, Abdelrahman Elbraky and Shaimaa Zaki Abdelmegied

Nephrology and Transplantation Department, Faculty of Medicine, Ain Shams University Hospital, Cairo, Egypt

Background and Aims: Bone disease post-transplantation is a major cause of morbidity in kidney transplant (KT) recipients, with a significantly higher risk of fractures and mortality. This study investigated the added value of calculated 10-year fracture risk for major osteoporotic fracture (MOF) and hip fracture by FRAX score with an assessment of risk factors in KT recipients.

Methods: A cross-sectional study included 71 live-related KT recipients. Demographic, clinical, and laboratory data were recorded. The 10-year fracture risk for MOF and hip fracture were calculated using FRAX score without bone mineral density in recipients who completed at least 1 year after KT.

Results: The prevalence of MOF (>3% risk of fracture) was 14.1% (10 patients), MOF (<3% risk of fracture) was 85.9% (61 patients). A high hip fracture score (>3% risk of hip fracture) was in 10% (1 patient). There was a significant difference between both groups (>3% vs <3% fracture risk) in age, MOF score, hip fracture score, and serum albumin p-value were <0.00001, <0.00001, 0.000134, and 0.043009 respectively. The analysis of demographic data of the patients with a score (>3% fracture risk) showed that 70% were males (7 patients), 50% (5 patients) had BMI >30 and the main cause of ESRD pre-transplant was lupus nephritis and glomerulonephritis in 50% (5 patients) that exposed for long periods of immune suppression pre-transplant. In 80% (8 patients) were 1st transplant, 10% (1 patient) were 2nd transplant, and 10% (1 patient) was a combined liver-kidney transplant. The rejection episode was zero%. There was a significant difference in patients’ fracture risk >3% in phosphorus pre-transplant versus post-transplant p-value 0.01.

Conclusion: FRAX score without bone mineral density has shown a low percent of fracture risk (<3%) in most kidney transplant recipients and high scores were associated with high BMI, phosphorus, and exposure pre-transplant to immune suppression.

Quality of Life as Represented by Physical Activity Was Improving After Full Correction of Post-Transplant Anemia

Hamed Alessa OTC, Nephrology, Kuwait

Background and Aims: Recent studies showed positive impact of correction of post-transplant anemia (PTA) on general health, exercise capacity, and
physical scores. So we conducted this prospective randomized controlled trial (RCT) to assess quality of life after full correction of post-transplant anemia in renal recipients receiving erythropoietin stimulating agents.

**Method:** We recruited 247 kidney transplant recipients with stable graft function in this RCT with 2 groups according to their target hemoglobin (11-12 g/dl, group 1, n = 183) and (13:15 g/dl group 2, n = 64) which was achieved using erythropoietin stimulating agents (ESA). Monthly clinical and laboratory evaluation of kidney graft function was carried out. Quality of life (QOL) was assessed - using 25 and 36 questionnaires at the start and 12 months.

**Results:** We observed more females in group 1 and the original kidney disease was chronic glomerulonephritis was significantly higher in group 2 (37.5%) followed by diabetic nephropathy (15.7%) while in group 1 it came as 25.7% and 22.4% respectively (p < 0.05). The studied groups were comparable regarding pre-transplant co-morbidities. Most patients received thymoglobin as induction and most of them were maintained on cyclosporine. We did not find any significant difference between the two groups concerning post-transplant co-morbidities (p > 0.05), however better graft function was observed in group 2 at 6 months (p < 0.05). At 12 months, the assessment of QOL using the Medical Outcomes Study 36-Item Short-Form Health Survey, group 1 showed better post-transplant physical features and higher emotional factors related inactivity at 12 month (p < 0.05), while group 2 showed significantly higher basal and 12 months activity state (p = 0.05). Basal inactivity was comparable in group 2 with that at 12 months (p > 0.05), emotional factors related inactivity was significantly higher at 12 months in group 1. Graft outcome was comparable between both groups (p = 0.125, (p = 0.005).

**Conclusion:** Quality of life as represented by physical activity was improving by full correction of PTA in renal transplant recipients receiving ESA.

**A STUDY OF CLINICAL PRESENTATION AND OUTCOME OF COVID 19 INFECTION IN KIDNEY TRANSPLANT RECIPIENTS**

Manzoor Parry1 and Shazad Alam2
1 Sher-i Kashmir Institute of Medical Sciences, Nephrology, Srinagar, India and 2Nephrology, Lucknow, India

**Background and Aims:** Novel coronavirus 19 (coronavirus disease-19 [COVID-19]) disproportionately affects patients with various kidney diseases. Patients with kidney transplant are at higher risk of complications of COVID-19 infection. Our aim of this analysis was to study the clinical profile and outcome of COVID-19 infections in KTRs from Kashmir.

**Method:** Here we present a cohort study of 122 KTRs with polymerase chain reaction-confirmed COVID-19 positivity from March 31, 2020 to October 31, 2022. We detailed demographics, immunosuppression regimen, clinical profile, Covid vaccination status, treatment given, and outcomes (acute kidney injury, graft failure and death) of our study population.

**Results:** Median age of the patients was 41 years and median age of disease was 2.9 years after transplant. Most common comorbidities included hypertension (65.6%) and diabetes (35.3%); presenting symptoms at the time of COVID-19 included fever (82.7%) and breathlessness (66.4%). Covid-19 vaccination was given to 81 patients (66.4%) with two doses in 26 patients and 55 patients received one dose. Clinical severity ranged from asymptomatic (4.1%), mild (36.1%), and moderate (28.7%), to severe (31.1%). Acute kidney injury developed in 46.7% of patients and mortality in 21 patients. Risk factors for mortality included higher age, severe disease, allograft dysfunction before COVID-19 infection, Obesity, acute kidney injury, absence of covid-19 vaccination. 

**Conclusion:** Mortality rates in COVID-19-positive KTR appear to be higher than those in nonimmunosuppressed patients. Risk factors for mortality included higher age, severe disease, allograft dysfunction before COVID-19 infection, Obesity, acute kidney injury, absence of covid-19 vaccination.

**THROMBOPROPHYLAXIS IN PEDIATRIC KIDNEY TRANSPLANTATION: A META-ANALYSIS**

MD Azharuddin and Manju Sharma
School of Pharmaceutical Education and Research, Jamia Hamdard, New Delhi, India

**Background and Aims:** Kidney transplant patients are at higher risk for developing renal graft thrombosis, especially in pediatric patients. Renal graft thrombosis mainly causes graft failure leading to high morbidity, mortality, and a significant impact on quality of life. To minimize the risk of renal graft thrombosis, antithrombotic prophylaxis is widely used. However, the effect of antithrombotic prophylaxis for kidney transplantation is still a matter of discussion. Therefore, we carried out a meta-analytic synthesis to determine the effect of antithrombotic prophylaxis in pediatric kidney transplantation patients.

**Method:** We systematically searched MEDLINE, CENTRAL, Cochrane Central Register of Controlled Trials, and Web of Science. The eligible studies were identifying the incidence of renal graft thrombosis, hemorrhagic complication (bleeding and bleeding severity), and adverse outcomes related to antithrombotic prophylaxis compared with control group (placebo, active treatment, and no antithrombotic prophylaxis). Meta-analysis was carried out using Review Manager 5.3. The random-effects model was used to compute the pooled estimates of risk ratio (RR) and 95% confidence intervals (CI).**

**Results:** A total of seven studies with 10,51 patients were included in the meta-analytic synthesis. Heparin was used across all the studies as the preferred antithrombotic prophylaxis. Results from the pooled meta-analysis reported that the overall risk for developing renal graft thrombosis was significantly lower in the antithrombotic prophylaxis group compared with the control group (RR = 0.81, 95% CI = 0.66-0.56, p = 0.003). There is no significant difference was found in incidence of hemorrhagic complications between antithrombotic prophylaxis and control group (RR = 0.81, 95% CI = 0.43-1.54). Similarly, there were no significant deaths were found in antithrombotic prophylaxis group compared with the control group (RR = 0.33, 95% CI = 0.01-22.45).

**Conclusion:** The results showed that antithrombotic prophylaxis significantly reduced the risk of renal graft thrombosis in pediatric kidney transplantation. However, due to limited outcomes, further real-world studies with long-term follow-up are required to generate sufficient data on the use of antithrombotic prophylaxis in pediatric kidney transplantation patients.

Abstracts
Background and Aims: Hypertension is one of the major health problems contributing to the development of cardiovascular diseases. In contrast to essential hypertension, which often displays complex pathogenesis due to multifactorial aetiology, several monogenic forms of hypertension are caused by mutations in genes associated with renal salt handling. Thus, studies on monogenic forms of hypertension could hold potential for novel therapeutic approaches for essential hypertension. Recently, increasing numbers of studies have demonstrated the alteration of the gut microbiome in pathological states including hypertension. These observations suggest the involvement of the intestinal microbiome in the development and/or maintenance of hypertension. A reciprocal congenic strain of Milan hypertensive rat (NA rat), harbouring a missense mutation in the gene encoding the alpha subunit of the membrane-skeletal protein adducin (Add1), develops hypertension starting from 3 months after birth. Preliminary studies on NA rats and its littermate Milan normotensive (MN) rats showed diverse expression patterns of renal sodium transporters/ion channels in two strains of rats, indicating a putative role of altered renal salt handling on the enhanced blood pressure in NA rats (unpublished data). Based on this background, the aim of this study was to investigate a possible connection between the gut microbiome and blood pressure phenotypes in these two strains. Furthermore, we evaluated whether the exchange of faeces between the two strains could transfer the phenotypes through the gut microbiome. Finally, mechanisms underlying the altered phenotype after microbiome exchange were investigated.

Method: Hypertensive NA rats and normotensive MN rats were subjected to ‘homogenization (HOM)’ of the microbiome after birth, which consisted of the exchange of bedding containing faeces from either strain, followed by co-housing of MN and NA rats in the same cage (MN-HOM and NA-HOM groups). For the baseline (BSL) condition, rats were homogenized within the same strain (MN-BSL and NA-BSL). At the age of 5 months, blood pressure measurement was performed using a non-invasive tail-cuff BP-2000 Blood Pressure Analysis system. Faeces from each rat were collected for microbiota metataxonomic analysis using next generation sequencing of 16S ribosome encoding DNA. At the end of the treatment, rats were sacrificed for the collections of blood and organs to assess the expressions of genes involved in renal salt reabsorption.

Results: Systolic blood pressure (SBP) in MN-BSL was averaged at 143.6 mmHg, while NA-BSL showed average SBP 163.3 mmHg, confirming the hypertensive phenotype in NA rats at baseline (P < 0.001). Interestingly, MN-HOM showed a significantly enhanced SBP compared to MN-BSL, reaching 153.5 mmHg (P = 0.005). On the other hand, the average SBP of NA-HOM was 163.7 mmHg, indicating that homogenization did not significantly impact blood pressure in NA rats. Although the MN-HOM group showed significantly increased SBP compared with MN-BSL group, the average SBP of MN-HOM was still significantly lower than both the NA-BSL and NA-HOM groups.

Different gut microbiota compositions were observed in the two strains of rats at baseline, and HOM altered both.

Conclusion: We have demonstrated that the hypertensive phenotype in NA rats was transferred to normotensive MN rats through the exchange of gut microbiota, indicating that the intestinal microbiota and/or metabolites derived therefrom could eventually modulate blood pressure. Further studies including immunoblotting as well as uremic toxin analyses are required to unveil the molecular mechanisms by which the gut microbiome modulates blood pressure.
blockade versus the monotherapies on top of RAS blockade in experimental diabetes.

Method: Twelve weeks old male and female uninefrectomized (UNx) db/db mice were treated for 8 weeks with an SGLT2i (empagliflozin, 10 mg/Kg/day five days a week) and/or a GLP1-RA (semaglutide, 10.0 nmol/kg twice per week) on top of a RAS blocker (ramipril, 8 mg/Kg/day). Vehicle-treated UNx db/db and non-diabetic (db/m) mice were included as controls. During the experiment weight, food and water intake, blood glucose, blood pressure (BP) and glomerular filtration rate (GFR) were measured. Kidney and heart were collected at the end of the experiment.

Results: The vehicle-treated UNx db/db showed increased body weight, food and water intake and blood glucose as compared to the vehicle-treated UNx db/m (Fig. 1A, B and C, p = 0.03, p<0.001 and p<0.0001, respectively). The GFR slope (ΔGFR, difference between final and basal GFR) was also significantly higher in the vehicle-treated UNx db/db vs the vehicle-treated UNx db/m (Fig. 1D, p = 0.02), a typical feature of incipient DN. All treatments significantly decreased systolic and diastolic BP as compared to vehicle-treated UNx db/db due to its ramipril component (Fig. 1E). Further, both empagliflozin and semaglutide (alone or combined) on top of ramipril lowered blood glucose in UNx db/db (Fig. 1C, p<0.001 vs vehicle UNx db/db in all cases) but semaglutide component maximized this effect. Food and water intake was decreased in UNx db/db treated with semaglutide on top of RAS blockade (alone or combined with empagliflozin) as compared to vehicle-treated UNx db/db (Fig. 1B) although no differences in body weight were noted between treated and untreated UNx db/db (Fig. 1A). A trend towards ΔGFR decline was observed in UNx db/db treated with empagliflozin and semaglutide on top of RAS blockade (Fig. 1D). Finally, heart weight but not kidney weight was significantly lower in all treated UNx db/db as compared to vehicle-treated UNx db/db (Fig. 1F).

Conclusion: Our preliminary results show that addition of semaglutide to empagliflozin therapy on top of RAS blockade could have synergic hypoglycemic effects. Further, although more research is needed, both empagliflozin and semaglutide in combination with ramipril trended to ameliorate diabetic hyperfiltration and decreased heart weight in a DN mouse model which suggests cardiorenal beneficial effects.

CRITICAL ROLE OF SERUM RESPONSE FACTOR IN PODOCYTE EPITHELIAL–MESENCHYMAI TRANSITION OF DIABETIC NEPHROPATHY

Long Zhao and Yan Xu

The Affiliated Hospital of Qingdao University, Nephrology, Qingdao, P.R. China

Background and Aims: To investigate the expression and function of serum response factor (SRF) in podocyte epithelial–mesenchymal transition (EMT) of diabetic nephropathy (DN).

Method: Expression of SRF, pSRF, synaptopodin, P-cadherin, ZO-1, α-SMA, FSP-1, fibronectin and collagen-1 were examined in podocytes or renal cortex following high glucose. SRF was upregulated by SRF plasmids and downregulated by CCG-1423 to investigate how SRF influence podocyte EMT in DN. Streptozocin was used to generate DM in rats.

Results: 1⃝ High glucose induced EMT and SRF upregulation in podocytes (Figure 1). High glucose suppressed synaptopodin and ZO-1 expression, and induced SRF, pSRF, collagen-1, FSP-1, α-SMA and Snail expression. SRF transferred from cytoplasm to nuclei obviously and the level of SRF was also increased in podocytes after high glucose treatment. 2⃝ SRF overexpression mediated EMT, migration and barrier dysfunction of podocytes (Figure 2). Overexpression of exogenous SRF reduced epithelial synaptopodin expression, and increased collagen-1, FSP-1, α-SMA and Snail expression in podocytes. Transwell chamber migration assay showed that overexpression of SRF significantly upregulated the migration of podocytes across the pores of transwell filters. Albumin filtration assay showed that albumin easily diffused across the monolayer of podocytes transfected with SRF cDNA. 3⃝ Inhibition of SRF preserved phenotypes of podocytes in vitro (Figure 3). CCG-1423 selectively

Figure 1:
suppressed the expression of pSRF and SRF in podocytes after high glucose stimulation. Besides, simultaneous treatment of podocytes with CCG-1423 also significantly abolished the reduction of synaptopodin expression and the induction of collagen-1, FSP-1, α-SMA and Snail expression. CCG-1423 also reduced the transfer of SRF from cytoplasm to nucleus in podocytes treated with high glucose.

The effect of CCG-1423 in diabetic rats (Figure 4—5). CCG-1423 significantly abrogated the reduction of synaptopodin expression and the induction of SRF, collagen-1, α-SMA and FSP-1 expression in renal cortex tissues. Masson and PAS staining demonstrated that renal glomerular fibrosis was present in DM group, and after 8 weeks treatment with CCG-1423, renal glomerular fibrosis was dramatically ameliorated. In addition, CCG-1423 significantly preserved P-cadherin expression and suppressed α-SMA and FN expression in DN rats. More importantly, CCG-1423 dramatically decreased 24-h urine protein excretion by about 50%, and increased serum albumin, compared with DM group.

Conclusion: Together, increased SRF activity provokes podocytes EMT and dysfunction in DN. Targeting SRF by small molecule inhibitor may be an attractive therapeutic strategy for DN.

Figure 4:
RENAL RENIN IS UPREGULATED BY THE COMBINATION TREATMENT OF EMPAGLIFLOZIN AND RAS BLOCKADE IN EXPERIMENTAL DIABETIC NEPHROPATHY

Ander Vergara Arana, Carmen Llorens Cebrià, Nerea Martos, Irene Martinez-Diaz, Frank Stein, Pamela Dominguez, Mireia Molina, Mandy Rettel, Begoña Benito, Sheila Bermejo Garcia, Michael Paul Pieper, Conxita Jacobs Cachá and Maria Jose Soler Romeo

1 Valld’Hebron Research Institute, Nephrology and Kidney Transplantation Research Group, Barcelona, Spain, 2 European Molecular Biology Laboratory, Proteomics Core Facility, Heidelberg, Germany, 3 Vall d’Hebron Research Institute, Cardiology Research Group, Barcelona, Spain and 4 Boehringer Ingelheim Pharma GmbH & Co KG, CardioMetabolic Diseases Research, Biberach an der Riß, Germany

**Background and Aims:** Sodium-glucose cotransporter 2 (SGLT2) inhibitors have proven to delay diabetic nephropathy (DN) progression on top of renin-angiotensin system (RAS) blockade. This protection is mainly attributed to improvement in renal hemodynamics, although direct effects on the kidney cannot be ruled out. The present study aimed to identify renal proteins differentially expressed between vehicle-treated diabetic mice and mice treated with empagliflozin, ramipril, or their combination, that could help explain the protective mechanisms of the drugs.

**Method:** Twelve weeks old diabetic db/db mice were given empagliflozin (10 mg/Kg/day), ramipril (8 mg/Kg/day), or the combination of both drugs during 8 weeks. Vehicle-treated db/db and db/m mice were used as controls. Serum glucose, blood pressure, GFR, and albuminuria were measured at baseline and at the end of the study. After 8 weeks, mice were euthanized, and the kidneys and serum were saved. A differential high-throughput proteomic analysis by mass spectrometry using isobaric tandem mass tags (TMT labelling) was performed in kidney cortex.

**Results:** Vehicle-treated db/db mice showed increased glycemia during the whole experiment, and empagliflozin reduced blood glucose. Ramipril treatment decreased blood pressure. Vehicle-treated diabetic mice also showed incipient DN with increased mesangial matrix and albuminuria compared to
their non-diabetic littermates. All the treatments reduced mesangial matrix expansion and albuminuria. Only 13 proteins were differentially expressed (false discovery rate $<5\%$ and Log$_2$FC $\geq 1$ or $\leq -1$) when comparing treated mice vs vehicle-treated db/db mice. The differentially expressed proteins were only identified between the mice treated with the combination of empagliflozin and ramipril and the vehicle-treated diabetic mice. Ramipril or empagliflozin alone did not produce significant changes in renal proteins. Kidney renin was evidently increased by the combination therapy with empagliflozin and ramipril, along with the tubular transporter scaffolding protein MAP17. The results were further validated through renin staining and renal renin concentration measurement. Renal renin concentration was increased by ramipril and further increased by the combination therapy with empagliflozin and ramipril when compared to vehicle-treated db/db mice (55 pg/µg (IQR:49–64), 94 pg/µg (IQR:71–102), and 112 pg/µg (IQR 104–116) in the groups treated with vehicle, ramipril and the combination of empagliflozin and ramipril respectively). However, renin serum concentration was similar between mice treated with ramipril and mice treated with the combination. Conclusion: The combined therapy of empagliflozin with ramipril upregulated renin in the kidney of a diabetic mouse model. The increase in kidney renin suggests that other mechanisms different from RAS act in the regulation of glomerular hemodynamics and arteriolar tone. Moreover, the increased sodium delivery to the macula densa does not inhibit renal renin secretion.

ROLE OF THE CGAS-STING PATHWAY IN THE PROGRESSION OF DIABETIC NEPHROPATHY

Sherif Khedr$^1$, Oleg Palygin$^2$ and Alexander Staruschenko$^3$

$^1$Physiology, Faculty of Medicine, Ain Shams University, Cairo, Egypt, $^2$Medicine, Division of Nephrology, Medical University of South Carolina, Charleston, United States of America and $^3$Molecular Pharmacology & Physiology, University of South Florida, Tampa, United States of America

Background and Aims: Diabetic kidney disease (DKD) is the leading cause of chronic renal pathology. Understanding the molecular underpinnings of DKD is critical to designing tailored therapeutic approaches. We have demonstrated previously that type 2 diabetic nephropathy (T2DN) rats develop renal and physiological abnormalities similar to clinical observations in humans with DKD, indicating these rats are an excellent model for studying the progression of renal injury in type 2 DKD [1]. Furthermore, our recent studies revealed sexual dimorphism in this model, indicating that while both male and female T2DN rats developed non-obese DKD phenotype, females had significant protection from the development of severe forms of glomerular and tubular damage [2]. The potential role of the cyclic GMP-AMP synthase (cGAS) / Stimulator of interferon genes (STING) pathway in renal inflammation and fibrosis was also uncovered [3]. Here we focused on sex differences in DKD and the potential mechanisms leading to the progression of DKD.

Method: To explore the sexual dimorphisms in the development of DKD, we utilized young (12-week-old) and aged (>48 weeks old) type 2 diabetic nephropathy (T2DN) rats. To delineate transcriptional changes, RNA-Seq analysis was performed in the kidney cortex of T2DN rats of both sexes at a younger and older age. Western blotting, immunohistochemistry, and flow cytometry analyses were further used to identify specific pathways contributing to sexual dimorphism and disease progression in T2DN rats.

Results: We have revealed that the cGAS/STING signaling pathway is upregulated in T2DN rats compared to non-diabetic Wistar rats and in type 2 diabetic human kidneys. The expression of key proteins in the cGAS/STING pathway, such as cGAS, STING, phospho-IRF, mitTFA, and TREX1, was significantly different between male and female T2DN rats and following the progression of DKD. Proinflammatory genes were also upregulated in male T2DN rats compared to female rats of the same age, and their levels were further elevated in aged rats. RNA-Seq analysis also identified significant changes in genes participating in the cGAS-STING inflammatory pathway. Flow cytometry revealed a significantly greater number of infiltrating leukocytes in the male kidneys compared to their age-matched females. Moreover, the leukocytic count was significantly higher in old males versus young males, while it was almost the same in females of different ages. Approximately 50% of the renal leukocytic population was monocytes/macrophages (CD11b/c$^+$), with fewer CD3$^+$ T cells, both CD3$^+$ CD4$^+$ and CD8$^+$ cytotoxic T cells, and CD45R$^+$ B cells.

Conclusion: Our study provides critical insights into the sexual dimorphism and progression of DKD and identifies the cGAS-STING pathway as an essential contributor to disease development.

**Background and Aims:** Type 2 diabetes mellitus (T2DM) is the first cause of end stage renal disease worldwide. Metabolite profiling is an emerging field of great significance, as T2DM prevalence is continuously rising. The subtle dynamics of gut microbiota derived metabolites may have important implications in diabetic kidney disease (DKD) development. Nitrogen metabolic pathway and retinoic acid signaling pathway seem to be rising. The subtle dynamics of gut microbiota derived metabolites may cause of end stage renal disease worldwide. Metabolite profiling is an important approach for understanding the interactions between gut microbiota and the host in the context of DKD.

**Method:** The serum and urine of 90 T2DM patients (P group) and 20 healthy subjects (C group), were assessed in a cross-sectional study, by ultra-high-performance liquid chromatography coupled with electrospray ionization-quadrupole-time of flight-mass spectrometry (UHPLC-QTOF-ESI+MS) techniques. P group was divided in 3 subgroups (normoalbuminuria-P1, microalbuminuria-P2, macroalbuminuria-P3). Statistical analysis was performed by untargeted multivariate (PLSDA, VIP scores, Random Forest, Biomarker analysis) and univariate (One Way ANOVA, Biomarker Analysis) methods. P1 vs. C1, P2 vs. C2, P3 vs. C3.

**Results:** Multivariate analysis, by which the P group vs. C group were compared, displayed: (1) in serum samples: increased levels (P<0.05) of all-trans retinoic acid, cysteine-S-sulfate, oleylglycine, threo-glycine and decreased levels (P<0.05) of phenylalanine, tyrosine, kynurenic acid; (2) in urine samples, there were increased levels of all-trans retinoic acid, indoxyl sulfate, serotonin sulfate and glycylprolylarginine. Subsequently, by applying univariate analysis, the biomarkers derived from gut microbiota were selected: (1) in serum samples: increased levels (P<0.05) of cysteine-S-sulfate, all-trans retinoic acid, cysteine-S-sulfate, and decreased levels (P<0.05) of phenylalanine, tyrosine, kynurenic acid; (2) in urine samples: increased levels (P<0.05) of all-trans retinoic acid, indoxyl sulfate, serotonin sulfate, and decreased levels (P<0.05) of phenylalanine, tyrosine, kynurenic acid.

**Conclusion:** The study suggests that ATRAs dynamic is disturbed in the normoalbuminuric stage of DKD. While its urinary levels correlated significantly with albuminuria, the changes observed in P1 subgroup, in serum and urine, may be correlated to the loss of renal tubular tight junction as a result of claudin downregulation. Phenylalanine and tyrosine, a part of nitrogen metabolic pathway, are indicators of the new-onset DKD. Their levels were upregulated in serum vs. urine, indicating their possible involvement in early DKD when comparing C vs. P1-P2-P3. Kynurenic acid and indoxyl-sulfate rise from tryptophan metabolism. Low levels in serum of kynurenic acid may suggest its possible implication in incipient endothelial dysfunction in DKD. Indoxyl-sulfate (IS) urinary excretion is dependent on albuminuria. The study shows an elevated excretion of IS, in the normoalbuminuric group compared to controls and may suggest a tubular damage that precedes the glomerular modifications in DKD.

**Conclusion:** UHPLC-QTOF-ESI+MS untargeted analysis reveals a particular metabolite fingerprint in early DKD. The study describes all-trans retinoic acid, phenylalanine, tyrosine, kynurenic acid, and indoxyl sulfate, as potential key biomarkers involved in early DKD pathogenesis, their levels being expressed in P1 subgroup compared with C group, and P2, P3 subgroups.

**ALTERNATIVE SPlicing IN MECHANICALLY STRETCHED PODOCYTES AS A MODEL OF GLOMERULAR HYPERTENSION**

Francescapaola Mattias1, Felix Kliewe5, Elke Hammer2, Sabine Ameling2, Chit Tong Lio3, Karlhends Endlich1, Uwe Zimmermann2, Sylvia Stracke3, Giovanni Bambattia Capasso4, Jan Baumbach2, Olga Tosy1, Uwe Volker2 and Nicole Endlich1

1Institute of Anatomy and Cell Biology, University of Medicine, Greifswald, Germany, 2Interfakultäres Institut für Genetik und Funktionelle Genomforschung, Abteilung für Funktionelle Genomforschung, Greifswald, Germany, 3Institute for Computational Systems Biology, University of Hamburg, Hamburg, Germany, 4Department of Urology, Greifswald, Germany, 5Department of Internal Medicine A, Greifswald, Germany and 6Department of Translational Medical Sciences, napoli, Germany

**Background and Aims:** It has been shown that mRNA splicing plays a relevant role in disease pathophysiology. However, the possible role of alternative splicing (AS) in hypertensive nephropathy (HN) has not been investigated. The purpose of the Sys_CARE (Systems Medicine Investigation of AS in Cardiac and Renal Diseases) project is to investigate the possible implication of AS events in HN development and progression.

**Method:** Differentiated murine podocytes were seeded on a flexible silicone membrane, and mechanically stretched using the Stretchy apparatus (NIPPOKA GmbH, Greifswald). Cells were stretched for 3 days under low and high stretch conditions with a frequency of 0.5 Hz. The mRNA and proteins were isolated and analyzed using RNA_SEQ and LC-MS/MS techniques. Enrichment analysis identified proteins which were classified according to the related biological processes, molecular function and cellular components. Splicing and transcript expression were evaluated with bioinformatical tools (rMATS, leafcutter, Whippet, MAJIO, IsoformSwitchAnalyzer).

**Results:** Proteomic analysis of cultured podocytes revealed significant difference expression levels for 135 proteins (54 increased and 81 decreased) and 424 proteins (195 increased and 229 decreased) under low and high stretch conditions, respectively, compared to unstretched conditions. Interestingly, most of the proteins with decreased intensity upon stretch are cytoskeleton and actin-binding proteins. In contrast, the up-regulated proteins are more associated in clusters affecting mRNA processing and splicing. By RNA_SEQ we identified over 1000 different splicing events including all types of alternative splicing events. We screened for candidates that showed an alternative splicing event in multiple tools, were found in the proteomics, were podocyte-specific, or showed altered expression in glomerulopathies such as diabetic nephropathy. In this regard, we found an isoform switch of My6 and Shroom3 after mechanical stretch.

**Conclusion:** Using mechanically stretched podocytes as a model of HN, we found significant up- and down-regulated proteins. In addition, by RNA_SEQ we identified an isoform switch of My6 and Shroom3 that might be essential for the development of HN.

**LANOSTEROL SYNTHASE RS2254524 POLYMORPHISM MODULATES SALT SENSITIVITY AND RENAL EXPRESSION IN A NOVEL MICE MODEL, LSSV643LV643L**

Lorena Citterio1,2, Sipontina Faienza3, Elisabetta Messaggio1, Laura Zagoto1, Chiara Livia Lanzani1,2,3, Marco Simionini1,2,3 and Paolo Manunta1,3,2

1IRCCS San Raffaele Scientific Institute, Genomics of Renal Diseases and Hypertension Unit, Milan, Italy, 2IRCCS San Raffaele Scientific Institute, Division of Nephrology and Dialysis, Milan, Italy and 3Università Vita Salute San Raffaele, Chair and School of Nephrology, Milan, Italy

**Background and Aims:** The blood pressure (BP) response to different salt intakes (salt sensitivity-SS), shows variability among individuals, with more frequency in hypertensives compared to the general population. Elevated levels of the Endogenous Oubain (EO) have been associated with hypertension (HT) and SS. We characterized the missense variation rs2254524 (Val642Leu; C>A) of the Lanosterol Synthase gene (LSS) coding for an enzyme in sterol biosynthesis, since AA patients on a low-salt diet showed a greater reduction in BP compared to the LSS CC, with only CC having an increase in plasma EO. Moreover, AKI incidence following cardiovascular surgery was greater among those with the LSS rs2254524 AA genotype than in those with the CC genotype. We aim at dissecting the functional correlation between LSS polymorphism, EO, SS-HT, and renal function.
Method: We generated by CRISPR-Cas9 a knock-in mouse model carrying the Lss V643L (Ls<sup>V635L/V635L</sup>) allele, homologous to Yv6L2 to dissect the functional correlation between LSS polymorphism, EO and salt-sensitive hypertension, and kidney expression. Male mice were fed with a normal-salt diet (0.5% NaCl), high-salt diet (4% NaCl), or low-salt diet (<0.03% Na) and BP was measured every two days by the tail-cuff system.

Results: Ls<sup>V6435L/V643L</sup> mice were viable, healthy, and undistinguishable phenotypically from WT. At baseline, the Ls AA affected kidney weight that was significantly enlarged at 3 (p = 0.02) and 12 months of age, compared to WT (kidney p = 0.04; liver p = 0.003). The Lss V643L mutation did not affect EO and SBP at 3 and 12 months, per se, but affects SBP responsiveness to salt intake. Indeed, we observed an increased SBP upon a high-salt diet only in Ls<sup>V6435L/V643L</sup> mice 12 months old compared to the control diet (p = 0.01). Moreover, the 12-month-old Ls<sup>V635L/V635L</sup> mice in high-salt diet showed labile hypertension and showed a higher incidence of heart fibrosis. At 12 months, in the adrenal gland of Ls<sup>V6435/V643</sup> mice, Lss mRNA level was reduced upon high-salt diet (p = 0.03), while RNA-seq analysis of renal differentially expressed genes revealed a different regulation of multiple Slc genes, both in control and high-salt diet, but also of Cbr2, and Arggap26.

Conclusion: The new Ls<sup>V6435/V643</sup> mouse model resembles the SS-HT phenotype together with EO non-responsiveness observed in HT patients, thus providing a good model of SS-HT. Our results reveal a role of Lss gene in the regulation of BP upon salt stimulus, and its influence at renal level at 3 and 12 months of age.

<sup>1</sup>Department Medical-Surgery Therapeutics, University of Extremadura, Badajoz, Spain; <sup>2</sup>IRCCS Ospedale San Raffaele, Nephrology and Dialysis, Milan, Italy; <sup>3</sup>IRCCS Ospedale San Raffaele, Genomics of Renal Diseases and Hypertension Unit, Milan, Italy; <sup>4</sup>Chair of Nephrology, University Vita Salute San Raffaele, Milan, Italy; and <sup>5</sup>Service of Nephrology, Badajoz University Hospital, Badajoz, Spain

**Background and Aims:** Hypertensive nephropathy is a common aging-related disorder. One of the main factors that contribute to the development of hypertension is salt intake. Based on blood pressure (BP) variation after sodium intake in an acute salt load test, individuals can be grouped in: sodium sensitive (SS), sodium resistant (SR) or inverse sodium sensitivity (ISS). Prostaglandin E2 (PGE2) is the main renal metabolite of the cyclooxygenase pathway, a major actor mediating renal injury and it has also been related to renal blood flow and hemodynamic changes. Our aim was to determine common, functional variants in genes involved in the PGE2 pathway to identify associations with the sodium sensitivity phenotype of hypertensive patients, as well as with parameters of renal function and BP traits.

**Methods:** We studied 511 treatment-naive hypertensive patients, who were subjected to an acute salt load test and consequently stratified into 173 SR, 172 SS patients and 166 ISS, after they showed an increase in BP values in these patients.

**Results:** In vitro, treatment of HK-2 cells with CoCl<sub>2</sub> decreased the expression of HIF-1<sub>α</sub> and it's translocation from cytoplasm to nucleus. Meanwhile, HIF-1<sub>α</sub> activation induced by CoCl<sub>2</sub> significantly increased lipid accumulation in HK-2 cells. Moreover, TGF-β and CTGF expression in HK-2 cells. The presence of glucose (30mM) made no significant difference to HK-2 cells incubated with CoCl<sub>2</sub>. HIF-1α mRNA expression significantly reduced lipid deposition in HK-2 cells incubated with CoCl<sub>2</sub>. In vivo study showed YC-1 treatment decreased the expression of HIF-1α in renal tubules of diabetic rats, which was accompanied by less lipid accumulation compared with the diabetes mellitus (DM) group. PAS staining showed the desquamation and necrosis of tubular epithelial cells in the YC-1 group were alleviated compared with the DM group. YC-1 treatment did not affect the ratio of kidney weight to body weight, whereas decreased the levels of blood glucose, urine albumin creatinine ratio and NAG creatinine ratio in diabetic rats. The expressions of fibrosis factor TGF-β and CTGF were decreased in the YC-1 group compared with the DM group. Furthermore, the protein expression of CPT1A, the key enzyme of fatty acid oxidation, which was decreased in the DM group compared with the controls, was regained by YC-1 treatment.

**Conclusion:** Our findings demonstrated that HIF-1α activation contributed to interstitial injury in diabetic nephropathy by inducing lipid accumulation.
HIF-1α activation might contribute to lipid nephrotoxicity by downregulating fatty acid oxidation.

**SODIUM-GLUCOSE COTRANSPORTER 2 INHIBITORS VERSUS DIPEPTIDYL PEPTIDASE 4 INHIBITORS AS STABILIZERS OF HIF PATHWAY IN DIABETIC NEPHROPATHY RATS**

**Background and Aims:** With the diabetes pandemic, chronic kidney disease is a burden, with diabetic nephropathy (DN) being the primary leading cause of end-stage renal disease. Antidiabetic drugs have shown renoprotective effects via different mechanisms, and among those are SGLT2 inhibitors and DPP-4 inhibitors. Hypoxia-inducible factor (HIF) pathway, a significant contributor to inflammation development in the kidneys, is a major pathway that regulates erythropoietin synthesis. Prolyl hydroxylase domain (PHD) decreases erythropoietin synthesis by inhibiting HIFs. PHD inhibitors are anticipated to have additional effects, such as protection against metabolic diseases, due to HIF’s impact on many genes. The diabetic kidney is characterized by enhanced HIF-1α activation but decreased HIF-2α activity. These actions may significantly contribute to glomerular and renal tubular dysfunction, renal inflammation and fibrosis, and decreased erythropoietin synthesis observed in DN. This work aims to test the renoprotective effect of SGLT2 inhibitors and DPP-4 inhibitors by controlling the proinflammatory and anti-inflammatory domains of the HIF pathway.

**Method:** Type 1 DM rat model was induced in 24-hour-fasted Sprague Dawley rats by a single intraperitoneal injection of 45 mg/kg streptozotocin (STZ). DM was verified by measuring blood glucose seven days following STZ injection, and only animals with glucose levels of ≥15 mM were included (n = 24), randomly and equally distributed, then received either saline or vildagliptin (3 mg/Kg) or empagliflozin (30 mg/Kg) once daily by oral gavage for three months. An additional group was used as a non-diabetic control. At the end of the experiment, rats were placed in metabolic cages for 24-h urine collection, then sacrificed. Blood samples and kidney tissue were collected.

Kidney function was assessed by measuring serum creatinine and urinary albumin: creatinine ratio. Regarding the HIF pathway as a potential mechanism, empagliflozin-treated groups showed a significantly higher HIF2α gene expression in kidney tissue samples (0.98 ± 0.10) than vildagliptin-treated group (0.58 ± 0.05). For the expression of its regulator, PHD3, there was a significant difference between groups (F = 5.694, p = 0.005). However, the vildagliptin-treated group (0.65 ± 0.06) didn’t differ significantly from the untreated group (0.60 ± 0.03), in contrast to the empagliflozin-treated group (2.01 ± 0.50), which showed a significantly higher expression than the other groups (Figure 1).

**Conclusion:** Empagliflozin significantly increased the level of HIF-2α in renal tissue. In addition, it nearly neutralizes the tubular expression of PHD3 compared to non-treated and vildagliptin-treated rats. SGLT2 inhibition is effective for correcting the proinflammatory/anti-inflammatory imbalance in DN.

**Results:** Vildagliptin and empagliflozin could significantly ameliorate the diabetic disturbance of renal function, as demonstrated in serum creatinine (F = 23.518, p < 0.001) with a non-significant difference between both treated groups, and in the significantly reduced albumin/creatinine ratio (F = 14.453, p < 0.001), with a significantly lower ratio for empagliflozin (4.73 ± 0.54) than vildagliptin-treated group (9.09 ± 1.04). Regarding the HIF pathway as a potential mechanism, empagliflozin-treated groups showed a significantly higher HIF2α gene expression in kidney tissue samples (0.98 ± 0.10) than the vildagliptin-treated group (0.58 ± 0.05). For the expression of its regulator, PHD3, there was a significant difference between groups (F = 5.694, p = 0.005). However, the vildagliptin-treated group (0.65 ± 0.06) didn’t differ significantly from the untreated group (0.60 ± 0.03), in contrast to the empagliflozin-treated group (2.01 ± 0.50), which showed a significantly higher expression than the other groups (Figure 1).

**Conclusion:** Empagliflozin significantly increased the level of HIF-2α in renal tissue. In addition, it nearly neutralizes the tubular expression of PHD3 compared to non-treated and vildagliptin-treated rats. SGLT2 inhibition is effective for correcting the proinflammatory/anti-inflammatory imbalance in DN.

**Figure 1:** Immunohistochemical staining of PHD3 in renal tubules. (A) Represents diabetic group with strong staining in about 80% of proximal tubules. (B): Vildagliptin treated diabetic group with moderate staining in about 30% of proximal tubules. (C): empagliflozin treated diabetic group with weak staining in about 20% of proximal tubules. (PHD3 × 400).
ENDOTHELIAL DYSFUNCTION IN PATIENTS WITH COVID-19 DURING ANTIOXIDANT THERAPY
Dano Egamberdieva1, Iroda Ruzmetova2 and Narine Raimkulova1
1Tashkent Pediatric Medical Institute, Internal Medicine, Nephrology and Hemodialysis, Tashkent, Uzbekistan and 2Internal Medicine, Nephrology and Hemodialysis, Tashkent, Uzbekistan

Background and Aims: In connection with the coronavirus pandemic of 2020, there have been recent discussions about the role of endothelial function in the course and prognosis of the disease. Purpose of the study, study of endothelial function in patients who have had a coronavirus infection.

Methods: Under observation were 60 patients who underwent COVID-19 of moderate severity on the 14th day of therapy at the age of 57 to 67 years. Patients of the 1st group (30 patients), against the background of standard basic therapy, were prescribed L-carnitine at a dose of 5 g/day for 5 days, followed by a maintenance dose of 1 g/day for 5 days. Group II consisted of 30 patients who met the inclusion criteria for the study, were treated for COVID-19 and did not receive metabolic agents. The state of endothelial function was assessed according to Doppler sonography of the brachial artery using the D.S. Celemajer (1992) using a reactive flush test. Changes in the diameter of the right brachial artery were assessed using a 7.5-12 MHz linear transducer with a phase grating ultrasound system En Visor C Philips. The results of the study were processed statistically using Student’s t test for paired and unpaired variables. Differences were considered significant at p<0.05.

Results: After analyzing the data of samples with RG in combination with blood flow velocity indicators, we noted that in response to an increase in blood flow velocity in the control group, the diameter of the brachial artery increased by almost 12%, in patients with COVID-19 from 20 to 25 cm. Male and obese placebo rats showed significantly, and the diameter of the artery practically did not change. Thus, with an increase in the mechanical stimulus, i.e. blood flow velocity in patients with COVID-19 did not occur a commensurate increase in the diameter of the vessel. The results obtained indicate a pronounced dysfunction of the endothelium in patients with COVID-19, in particular, EDV, the indicators of which were two times lower than the control values.

Conclusions: The inclusion of L-carnitine in the regimen of standard therapy for patients with COVID-19 significantly improves the values of EVR compared to the standard basic therapy.

NEXHOPROTECTIVE EFFECTS OF SEMAGLUTIDE IN A MOUSE MODEL OF HYPERTENSION-ACCELERATED DIABETIC KIDNEY DISEASE
Michael Christensen1, Louise S. Dalboge1, Martin Ronn Madsen3, Henrik Bjørk Hansen1, Rune Ida1 and Mette Viberg Østergaard2
1Gubra aps, Denmark and 2Tribune Therapeutics, Norway

Background and Aims: Obesity, hyperglycemia and hypertension are critical risk factors for development of diabetic kidney disease (DKD). Emerging evidence suggests that glucagon-like peptide-1 receptor (GLP-1R) agonists improve cardiovascular and renal outcomes in type 2 diabetes patients. Here, we characterized the effect of long-acting GLP-1R agonist semaglutide alone and in combination with an ACE inhibitor in a model of hypertension-accelerated, advanced DKD facilitated by adeno-associated virus-mediated renin overexpression (ReninAAV) in uninephrectomized (UNx) female db/db mice.

Method: Seven weeks after ReninAAV administration and six weeks post-UNx, db/db UNx-ReninAAV mice were administered (q.d.) vehicle, semaglutide (30 nmol/kg, s.c.) or semaglutide (30 nmol/kg, s.c.) + lisinopril (30 mg/kg, p.o.) for 11 weeks. Endpoints included tail-cuff blood pressure evaluation at week 1 and 10, plasma/urine biochemistry, kidney histopathology as well as RNA sequencing.

Results: Semaglutide robustly reduced hyperglycemia, hypertension and albuminuria concurrent with notable improvements in glomerulosclerosis severity, urine/renal kidney injury molecule-1 (KIM-1) levels. Furthermore, semaglutide suppressed gene expression markers of extracellular matrix modelling and immune system activation. Co-administration of lisinopril further ameliorated hypertension, glomerulosclerosis as well as markers of fibrogenesis and inflammation.

Conclusion: Semaglutide improves disease hallmarks in the db/db UNx-ReninAAV mouse model of advanced DKD. Renal outcomes were further improved by combined antihypertensive standard-of-care. These data display the translatability of the db/db UNx-ReninAAV mouse model of DKD.

RENAI INJURY IN RELATION TO OBESITY AND THE ADDITIVE EFFECT OF HYPERTENSION IN FEMALE AND MALE OBESE AND LEAN ZSF1 RATS
Isabel T.N. Nguyen1, Maarten Jan Cramer2, Jaap A. Joles3 and Marianne Verhaar1
1University Medical Center Utrecht, Nephrology and Hypertension, Netherlands and 2University Medical Center Utrecht, Cardiology, Netherlands

Background and Aims: Chronic kidney disease co-exists with heart failure with preserved ejection fraction (HFpEF), which is characterized by the presence of obesity, hypertension, and diabetes mellitus type 2. Obese ZSF1 rats, a model of HFpEF, exhibit multiple of these comorbidities that can disturb cardiac function. Little attention has been paid to how these comorbidities affect renal disease in the ZSF1 rats. HFpEF is found predominantly in women in whom obesity and hypertension are particularly prevalent. Therefore, we aimed to characterize the renal phenotype in female and male, lean and obese, ZSF1 rats and investigated additional effects of worsened hypertension on disease severity.

Method: Systolic blood pressure and renal function were assessed biweekly in female and male, lean and obese, ZSF1 rats from 12 to 26 weeks of age by tail-cuff plethysmography, urine collection via metabolic cages and plasma collection, respectively. From 19 weeks of age, rats were implanted with either a deoxycorticosterone acetate pellet (DOCA) and fed a high salt diet (6% NaCl) or with a placebo pellet and fed a normal salt diet. At 26 weeks of age, terminal GFR was assessed via inulin clearance under isoflurane. Renal sections were processed for histological analysis.

Results: Lean placebo ZSF1 rats, both female and male, were mildly hypertensive (systolic blood pressure 140-150 mmHg). All obese rats showed HFpEF, elevated by a low ratio. In female normoglycemic ZSF1 rats, obesity associates with mild proteinuria, decreased GFR and glomerular hypertrophy. The addition of DOCA-salt worsened hypertension in female obese ZSF1 rats, but not in their lean counterparts. DOCA-salt-worsened hypertension enhanced proteinuria and triggered glomerulosclerosis in female obese rats. Male obese placebo ZSF1 rats were hyperglycemic and showed proteinuria, glomerular hypertrophy and sclerosis, and tubulo-interstitial damage. DOCA-salt worsened hypertension in both male lean and obese rats and further aggravated proteinuria, tubulo-interstitial damage, glomerular hypertrophy and sclerosis in obese male rats. No effect of DOCA-salt was observed on GFR in both male and female ZSF1 rats.

Conclusion: Female obese ZSF1 rats developed mild renal disease and DOCA-salt-worsened hypertension deteriorated renal function and structure in normoglycemic female obese ZSF1 rats similar to hyperglycemic male obese ZSF1 rats.

ACCS2 AGGRAVATES RENAL TUBULAR INFLAMMATION BY INDUCING THE DYSREGULATION OF FATTY ACID METABOLISM AND MITCHONDRIAL OXIDATIVE STRESS IN DIABETIC MICE
Jian Lu and Chun-Ming Jiang
Department of Nephrology, Nanjing Drum Tower Hospital, the Affiliated Hospital of Nanjing University Medical School, Nanjing, P.R. China

Background and Aims: Treatment options for diabetic nephropathy (DN) are currently limited. Chronic renal inflammation has been widely recognized as a major promoter of DN. The tubular epithelial cells are a major source of IL-1β in diabetic db/db mice. Inhibition of Acetyl CoA Synthase 2 (ACCS2) has been shown to promote high-fat diet-induced liver injuries, but the underlying mechanism of action of ACCS2 in diabetic renal injuries has not been elucidated.

Method: Strepotozocin (STZ) was intraperitoneally injected to establish the diabetic mouse model. We investigated the effects of ACCS2 on diabetes-induced renal tubular injury in transgenic mice with global accs2 knockout (acss2−/−). PAS staining was carried out to evaluate pathological injury of kidneys in mice. The renal tissue immunostaining was conducted to detect IL-1β expression and macrophage distribution in kidney tissues of mice. HK-2 cell culture model was achieved by high glucose stimulation in vitro. Real-time PCR analysis was applied to evaluate gene expression of inflammatory factors IL-1β, TNF-α, and MCP-1. Western Blot and immunofluorescence staining were conducted to detect the activation of the NLRP3 pathway and mitochondrial reactive oxygen species (ROS).

Results: ACCS2 was upregulated in STZ-induced diabetic renal tubular cells, which is significantly co-expressed in IL-1β-positive renal tubular cells of STZ-induced diabetic mice. The mice with acss2−/− exhibited decreased renal tubular inflammation and inhibited NOD-like receptor protein 3 (NLRP3)
Diabetes is a common co-morbidity in patients with end stage renal disease (ESRD) receiving renal replacement therapy (RRT). Glucose-lowering therapies (GLT) such as sulphonylureas and insulin are commonly used treatments in diabetes but increase the risk of hypoglycaemia. Dialysis is also a risk factor for hypoglycaemia due to reduced drug clearance, decreased gluconeogenesis and glucose loss into the dialysate. Guidelines suggest an HbA1c target of 58 mmol/mol for patients with ESRD receiving glucose lowering therapies, given that tight HbA1c control has not been shown to improve cardiovascular risk, and HbA1c <58 mmol/mol will incur risk of hypoglycaemia in a potentially vulnerable population. We evaluated the clinical and demographic features associated with HbA1c <58 mmol/mol in an ESRD cohort aiming to define characteristics that predict the need for closer glycaemic monitoring.

Method: We performed a retrospective observational study of patients receiving RRT and treated with GLT attending a single centre nephrology unit using data collected from a clinically used electronic database. Patients with HbA1c <58 mmol/mol in the last 12 months were identified. Clinical, biochemical and demographic factors were compared between groups. Depreciation was measured using the Scottish Index of Multiple Deprivation (SIMD), whereby 1 represented the most deprived areas within Glasgow, while 5 represented the most affluent. Between group characteristics were analysed using Pearson’s Chi-squared test or Wilcoxon test, and logistic regression was used to evaluate factors contributing to hypoglycaemia.

Results: We identified 607 patients, 51.6% of whom had an HbA1c below 58 mmol/mol. 298 patients were on haemodialysis, 14 on peritoneal dialysis and 291 had a kidney transplant. Patients with HbA1c <58 mmol/mol were older, (58±16.8 vs 60±15.15 years, p = 0.004) but there was no difference in duration of diabetes (9.1±10.2 vs 8.3±12.3 years, p = 0.42) or ESRD vintage (4.6±6.9 vs 4.1±7.5 years, p = 0.44). There was a higher proportion of type 2 diabetes in the group with HbA1c <58 mmol/mol (26% vs 36%, p = 0.04). There was no association between HbA1c and SIMD (p = 0.46) nor gender (p = 0.55). In logistic regression, increasing age (OR 1.19, 95% CI 1.03, 1.38) and ESRD vintage (OR 1.03, 95% CI 1.01, 1.06) increase the likelihood of tight glycaemic control. Transplantation reduced the risk (OR 0.64, 95% CI 0.44, 0.93). There was no association between type of GT and risk of tight glycaemic control. Subgroup analyses of the haemodialysis and transplant populations was also performed with broadly similar findings. In patients on haemodialysis, increasing age and ESRD increased the risk of HbA1c <58 mmol/mol. In patients with a kidney transplant, there was no association between current estimated glomerular filtration rate and HbA1c <58 mmol/mol.

Conclusion: Tight glycaemic control is very common in patients with ESRD on GT. Tight glycaemic control may be beneficial in patients with type 2 diabetes receiving haemodialysis, increasing age, and ESRD vintage, increased risk of tight glycaemic control and hypoglycaemia. Transplantation was a substantial protective factor. In patients with a kidney transplant, no trend was found in eGFR and HbA1c. This is a huge concern and suggests HbA1c checks need to be included as part of regular renal profile monitoring every 3 months. More regular follow-up with the Diabetes team may also be useful in this patient group. Continuous glucose monitoring (CGM) devices have revolutionised diabetes care by allowing easy access to data such as time in range and trends in blood sugar throughout the day, thus making it easier to optimise treatment. These devices also provide the patient with a warning when they are approaching hypoglycaemia. This study provides an argument that existing indications for CGM do not match risk factors for tight glycaemic control in ESRD. Hypoglycaemia is difficult to predict in ESRD patients and access to CGM should be widened.
THE ASSOCIATION BETWEEN HEMOGLOBIN A1C LEVEL AND COMPLICATIONS IN PATIENTS WITH DIABETES AND ADVANCED CHRONIC KIDNEY DISEASE

Dea Kofod1, Nicholas Carlson1, Tobias Bomholt1, Thomas Peter Almdal2, Jesper Svendsen3, Gunnar Gislason4, Christian Torp5, Bo Feldt-Rasmussen1 and Mads Hornum1

1Rigshospitalet, Department of Nephrology, Copenhagen, Denmark, 2Rigshospitalet, Department of Endocrinology, Copenhagen, Denmark, 3Rigshospitalet, Department of Cardiology, Copenhagen, Denmark, 4Gentofte Hospital, Department of Cardiology, Hellerup, Denmark and 5North Zealand Hospital, Department of Cardiology, Hillerød, Denmark

Background and Aims: Although the global prevalence of advanced diabetic kidney disease is increasing, the optimum glycemic target remains uncertain. Specifically, data pertaining to the association of hemoglobin A1c (HbA1c) level with micro- and macrovascular outcomes in patients with advanced diabetic kidney disease remain inconclusive. We examined the association between HbA1c levels and complications in patients with diabetes and chronic kidney disease (CKD) stage 4 and 5.

Method: In a Danish nationwide registry-based retrospective cohort study, we included persons ≥18 years of age with diabetes, an estimated glomerular filtration rate (eGFR) <30 mL/min/1.73m2 and a concurrent measured HbA1c between 2010 and 2022. Complications were categorized as 1) major adverse cardiovascular events (MACE) defined as a composite endpoint of acute myocardial infarction, stroke, and all-cause mortality; 2) microvascular complications defined as a composite endpoint of diabetic retinopathy, major lower extremity amputation, and start of dialysis; 3) hospitalization with hypoglycemia. Multiple outcome-specific Cox regressions stratified by HbA1c levels were performed to calculate the 1-year risk of complications standardized to the distribution of risk factors of all patients in the sample. The analyses regarding the risk of hypoglycemia were further stratified according to insulin treatment at baseline.

Results: In total, 34,046 patients were included. The median age was 76.2 (IQR 69.1-82.7) years and 54.6% were men. The median eGFR and HbA1c level was 26.4 (IQR 21.9-28.5) mL/min/1.73m2 and 53 (IQR 46-63) mmol/mol, respectively. Figure 1 depicts the 1-year risks of MACE and microvascular complications stratified by HbA1c level. We found a U-shaped association between HbA1c level and MACE where patients with an HbA1c level between 45-50 mmol/mol had the lowest risk. The risk increased significantly with an HbA1c level below 45 mmol/mol or above 65 mmol/mol compared with 45-50 mmol/mol (P<0.001). The risk of microvascular complications was lowest at an HbA1c level between 35-40 mmol/mol. The risk increased significantly with increasing levels of HbA1c above 50 mmol/mol compared with 35-40 mmol/mol (P<0.05). The 1-year risks of hospitalization with hypoglycemia stratified according to HbA1c level and insulin treatment are illustrated in Figure 2. For both groups, the risk was lowest at an HbA1c level between 30-40 mmol/mol and increased with increasing HbA1c levels.

Conclusion: In patients with diabetes and CKD stage 4 and 5, HbA1c levels >65 mmol/mol and <45 mmol/mol were associated with an increased risk of MACE, whereas HbA1c levels >50 mmol/mol were associated with a higher risk of microvascular complications. Our findings suggest that appropriate glycemic control can reduce adverse outcomes in patients with advanced CKD without increasing the risk of hypoglycemia, but also suggest that intensive glycemic control (HbA1c <45 mmol/mol) might be associated with an increased risk of MACE.
Figure 1: The 1-year risk of major adverse cardiovascular events and microvascular complications with 95% confidence intervals stratified by HbA1c level.

Figure 2: The 1-year risk of hospitalization with hypoglycemia with 95% confidence intervals stratified by HbA1c level and glucose-lowering treatment.

DOES RENAL ASYMMETRY WITH HYPERTENSION EQUAL RENAL ARTERY STENOSIS?
R. Haridian Sosa Barrios1,2, Adriana Maria Cavada Bustamante, Aina Quiliu1, Pablo Díez1, Sanz Clara1, Víctor Burguera Vion1,2, Milagros Fernández Luco1,2,3 and Maite Rivera1,2,3
1Hospital Universitario Ramón y Cajal, Nephrology, Madrid, Spain, 2Grupo de Nefrología Diagnóstica e Intervencionista de la Sociedad Española de Nefrología, Madrid, Spain and 3Universidad de Alcalá de Henares, Medicina, Spain

Background and Aims: Renal ultrasound (US) is a basic imaging study in renal disease with hypertension (HTN) work up. Asymmetry is a frequent finding but it does not equal renal artery stenosis (RAS). Our aim was to describe the incidence of asymmetry findings in our Diagnostic and Intervisional Nephrology Unit (DINU) and study its correlation with HTN and RAS.

Method:

- Retrospective data collection within our DINU ultrasound database from January 2020 until May 2022. An experienced interventional nephrologist performed all US studies and all US were requested by nephrologists. Search terms included asymmetry, renal atrophy, RAS, stent, kidney malrotation and solitary kidney.
- Control group were all US defined as normal in the same study period. Those with polycystic kidney disease or surgical nephrectomy were excluded.
- Asymmetry was defined as more than 1.5 cm / 10% difference in longitudinal size between both kidneys.
- Demographic data, estimated glomerular filtration rate (eGFR) as per CKD-EPI equation, US request reason and findings were recorded. On those with HTN, number of antihypertensive medications and blood pressure (BP) measurements were also collected.

Results:

2454 US were done in the study period. US was requested due to chronic kidney disease work up in 29%. Urological alterations (hydrenephrosis and kidney scars) were found in 19.7%.
- 78.4% had HTN and 19.7% required more than 3 antihypertensive medications.
- Mean eGFR was 57.61 ± 30 ml/min/1.73 m².
- 51 (2.1%) were diagnosed as renal asymmetry, of which 11 (21.5%) were secondary to RAS confirmed by Doppler US. Doppler US confirmed RAS in 90.9%.
- Mean asymmetry was 2.46 cm and right kidney was the smaller in 67.5%.
- In 37% of those with asymmetry a complementary study was requested (nuclear study or CT angiogram)→ 13.7% had asymmetry without any other related pathology.
- HTN incidence in the asymmetry group without RAS was higher with statistical significance (40 vs 22, p < 0.05), and they required more antihypertensive medications than those in the control group (1 ± 2.09 vs 0.214, p < 0.05) to achieve acceptable BP control as per guidelines.
- Those with asymmetry without RAS had worse hypertension and their BP was toughest to control (32 vs 22, p < 0.05).

Conclusion: Renal asymmetry is infrequent (2%) and in up to a quarter of those this finding is related to RAS. In our experience, asymmetry associates with hypertension even if no RAS is present: renal asymmetry associates with higher hypertension prevalence and higher medication requirements to reach acceptable blood pressure control.

PREDICTING NON-DIABETIC KIDNEY DISEASE IN PATIENTS WITH TYPE 2 DIABETES MELLITUS: EXTERNAL VALIDATION OF FOUR PREDICTIVE MODELS
Deborah Soledad Roldán, Angela Rey, Enrique Gruss and Amir Shabaka
Hospital Universitario Fundación Alcorcón, Nephrology, Alcorcón, Spain

Background and Aims: Several prediction models have been published for estimating the probability of non-diabetic kidney disease in kidney biopsies performed in patients with diabetes mellitus. External validation and comparison of these models is essential prior to their clinical application. The aim of this study was to validate and compare the predictive capacity of four previously described clinical models as a tool to predict non-diabetic kidney disease (NDKD) in diabetic patients.

Method: We retrospectively reviewed kidney biopsies performed in patients with type 2 diabetes mellitus between January 1999 and December 2022 in our centre. The probability of presence of NDKD was calculated by using the clinical and laboratory parameters at the time of the decision to perform a biopsy, according to 4 models: Surinrat’s model, Liu’s model, Li’s model and Garcia-Martin’s model (see Table 1). Overall model fit was assessed, calibration curves were plotted and discrimination for each model was assessed by using the receiver operating characteristic (ROC) curve in line with the transparent reporting of a multivariable prediction model for individual prognosis or diagnosis (TRIPOD) guidelines.

Results: The study included 280 patients, 68.9% were males and the mean age was 65.4 ± 11.9 years. 172 patients (61.4%) had a diagnosis of non-diabetic kidney disease. On calculating the risk of NDKD, Surinrat’s, Li’s and Garcia-Martin’s models predicted 33.6%, 64.8% and 53.4% of NDKD when using the “probable NDKD” threshold, and 60.7%, 81% and 90.7% respectively when including the “grey zones”. Fleiss’ Kappa test showed a fair agreement between the four models when using the “probable NDKD” threshold, and 64.2% respectively while decreasing in Garcia-Martin’s model to 64.2%. Area under the ROC curve (AUC) was higher in Garcia-Martin’s model (AUC 0.66, 95% CI 0.58-0.74, p < 0.001) compared to Lin’s model (AUC 0.59, 95% CI 0.50-0.67, p = 0.044), while Surinrat’s and Liu’s models did not discriminate (AUC 0.55, 95% CI 0.47-0.64, p = 0.214 and AUC 0.58, 95% CI 0.49-0.63, p = 0.084).

Conclusion: There is a fair agreement between the four models for predicting non-diabetic kidney disease in type 2 diabetic patients. Of the models studied, Garcia-Martin’s model most accurately predicted non-diabetic kidney disease in type 2 diabetes patients, although discrimination remained poor. These models may not be suitable for guiding clinicians on indicating a kidney biopsy in diabetic patients in our population.

KIDNEY BIOPSY IN PATIENTS WITH TYPE 2 DIABETES: A SINGLE CENTER OBSERVATIONAL STUDY

Inês Alexandre, Andreia Curto, Fábio Henriques, Mariana Ramos, Catarina Brás, Afonso Santos, Pedro Campos, Fernando Domingos and Ana Pires

Hospital Prof. Dr. Fernando Fonseca, Portugal

Background and Aims: Patients with type 2 diabetes mellitus (T2DM), may have various underlying causes contributing to kidney disease beyond diabetic nephropathy (DN). In such cases, a kidney biopsy (KB) can provide a definite diagnosis and allow for tailored treatment options. The aim of this study is to evaluate non diabetic kidney disease (NDKD) in T2DM patients and identify data to support KB indications.

Method: This is a retrospective observational study that included patients with T2DM who were submitted to a native KB between 2011 and 2022. We collected demographic, clinical and laboratory data at the date of biopsy. KB indication was considered in order to include the patients in the first encountered criteria defined sequentially as the presence of (1) nephrotic syndrome, (2) low or rapidly declining estimated glomerular filtration rate (eGFR), (3) nephrotic proteinuria and (4) hematuria.

Results: We analysed 72 patients with T2DM that were submitted to KB (Table 1). All except one patient had hypertension and 38 patients were screened for diabetic retinopathy (DR), which was present in 23 patients.

Table 1: Demographic and clinical characteristics of patients submitted to KB.

ns – not significant (p-value > 0.05)
Diabetic kidney disease (DKD) is a common complication of type 2 diabetes (T2DM) and is associated with increased mortality and morbidity. The diagnosis of DKD is based on the presence of proteinuria (with a protein-to-creatinine ratio (pPCR) ≥ 30 mg/mmol) and declining estimated glomerular filtration rate (eGFR) (≤ 60 mL/min/1.73 m²). However, the absence of DKD does not exclude the presence of diabetic kidney disease (DKD) with or without non-diabetic kidney disease (NDKD) in T2DM patients.

### #3505 DIAGNOSING HYPERTENSION IN HEMODIALYSIS PATIENTS USING HOME VERSUS ROUTINE PERIDIALYTIC BP MEASUREMENTS

**Kallitheni Leonidou1, Panagiotis Georgiannos1, Anastasios Kollias2, Ioannis Kontogiorgos3, Vasilios Vaios1, Apostolos Karligkiotis1, Konstantinos Mavromatis3, Pantelis Zebekakis2, George Stergiou2 and Vassilios Liakopoulos4**

1AHEPA Hospital, Aristotle University of Thessaloniki, 1st Department of Medicine, Thessaloniki, Greece, 2Sotiria Hospital, National and Kapodistrian University of Athens, Hypertension Center STRIDE-7, 3rd Department of Medicine, Athens, Greece, 3Therapeutiki Dialysis Center, Thessaloniki, Greece and 4AHEPA Hospital, Aristotle University of Thessaloniki, 1st Department of Medicine, Thessaloniki, Greece

**Background and Aims:** Although routine blood pressure (BP) measurements taken shortly before or after dialysis provide imprecise reflection of interdialytic ambulatory BP, this method continues to form the basis for the diagnosis of hypertension among patients on hemodialysis. Home BP monitoring (HBPM) is a guideline-recommended technique that may improve the diagnosis of hypertension in this population. Using 44-hour ambulatory BP monitoring (ABPM) as the reference-standard method, this study aimed to compare the diagnostic performance of home versus routine pre- and postdialysis BP recordings in hemodialysis patients.

**Method:** In 70 stable patients with end-stage kidney disease receiving thrice-weekly hemodialysis, BP was assessed with the following methods: (i) routine predialysis and postdialysis BP measurements averaged over 2 weeks; (ii) HBPM for 7 days (dublate morning and evening measurements, Microlife WatchBP Home N); (iii) ABPM (20 min intervals over an entire interdialytic interval - 44 hours, Microlife WatchBPO3).

**Results:** The mean age of the patients was 65±3.13 years; 45 patients (64%) were males, and 62 (88.7%) had a known history of hypertension. The mean 95% confidence interval (CI) of the difference between ambulatory systolic BP (SBP) and (i) predialysis SBP was 11.43 (8.24, 14.62) mmHg, (ii) postdialysis SBP was 3.9 (0.37, 7.56) mmHg, and (iii) home SBP was 8.61 (6.05, 11.17). The area under the receiver operating characteristic curve for the detection of an ambulatory daytime SBP ≥ 135 mmHg was significantly higher for home BP measurements 0.934 (95% CI: 0.871-0.996) as compared to predialysis 0.778 (95% CI: 0.643-0.913) and postdialysis 0.766 (95% CI: 0.623-0.909) BP recordings (P = 0.02 for both comparisons). 1-week average home SBP at the cut-off point of 141.0 mmHg provided the best combination of high sensitivity (85.7%) and high specificity (92.9%) in diagnosing systolic ambulatory hypertension.

**Conclusion:** The present study shows that among patients on hemodialysis, HBPM for 1 week provides greater accuracy than 2-week averaged routine pre- and postdialysis BP recordings in the diagnosis of hypertension confirmed by the reference-standard method of interdialytic ABPM.

---

**ANTIHYPERTENSIVE PRESCRIBING PATTERNS IN CKD: FINDINGS FROM THE SALFORD KIDNEY STUDY**

**Rajkumar Chinnadurai1,2, Hon Lin Henry Wu1, Jones Abumara1,2, Sharmilee Renganarajan1, Darren Green1,2 and Philip A. Kalra1,2**

1Salford Care Organisation, Northern care Alliance NHS Foundation Trust, Department of Renal Medicine, Salford, United Kingdom and 2Faculty of Medicine, Medicine and Health, University of Manchester, Manchester, United Kingdom

**Background and Aims:** Hypertension is the second leading cause of chronic kidney disease (CKD) following diabetes and occurs in most patients with CKD. Finding an optimal treatment regime for hypertension remains challenging due to the complex bidirectional cause-and-effect relationship between hypertension and CKD, and hypertensive CKD patients may require treatment with multiple antihypertensive drugs. Database studies and practice guidelines have continued to demonstrate international variability in antihypertensive treatment practices. We analysed data from the Salford Kidney Study (SKS) database in relation to antihypertensive prescribing patterns among study patients.

**Method:** The SKS is an ongoing prospective study recruiting patients with CKD since the year 2002. Data including patient demographics, comorbidities, physical parameters, concurrent medications, and biochemical results are collected at baseline (study enrolment). All patients are followed up annually until they reach their endpoints [reaching end-stage kidney disease (ESKD), death, or discharge from follow-up] individually, with updates in their medical records including a list of medications. We have used Cox regression analysis and Kaplan Meier charts to investigate the associations between Renin-Angiotensin-Aldosterone System inhibitor (RAASi) use and the number of antihypertensive agents (binary groups of ≤ 3 or > 3), and clinical outcomes (ESKD and all-cause mortality).

**Results:** A total of 3230 patients recruited between October 2002 and December 2019 were included in this analysis. At baseline, the median age of the cohort was 67 years with a predominance of males (62%) and those of white ethnicity (96%), 90% had a history of hypertension and 32% were diabetic. The median blood pressure was 138/75 mmHg. Previous myocardial infarction was recorded in 15%, congestive cardiac failure in 17% and cerebrovascular disease in 7.7% of the patients. The median estimated glomerular filtration rate (eGFR) was 30 ml/min/1.73 m² and the median urine protein creatinine ratio (uPCR) was 35 mg/mmol. RAASi agents (ACEi & ARB) (56%) were the most common antihypertensive medications to be prescribed, followed by diuretics (50%), calcium channel blockers (45%), and beta blockers (34%). The proportion of patients prescribed RAASi was associated with greater proteinuria (43 vs 33%, p < 0.001). CKD patients with preexisting cardiovascular comorbidities were more likely to be prescribed beta blockers (44 vs 27%, p < 0.001), diuretics (58 vs 39%, p < 0.001) and mineralocorticoid antagonists (6.4 vs 1.85%, p < 0.001). An increasing number of CKD patients were being prescribed ARBs over 24-month follow-up (34 vs 28%, p = 0.02). In a multivariable Cox-regression analysis, RAASi intake was not associated with reaching ESKD (HR 0.91; p = 0.49) but was associated with a significant survival benefit (HR 0.84; p = 0.001) (Figure 1). Use of a higher number of antihypertensive agents (i.e. > 3) was associated with both greater mortality (HR 1.28; p = 0.02) and worse dialysis-free survival (HR 1.46; p = 0.007) (Figure 2).

**Conclusion:** Antihypertensive prescribing patterns in the SKS were consistent with current guidelines in the U.K. (e.g. NICE guidance 2022), with RAASi being predominantly prescribed as the first-line antihypertensive agent. An overall survival benefit was noted with RAASi use, although there was no signal for reducing progression towards ESRD. Outcomes were poor in patients with resistant hypertension needing multiple antihypertensive agents. Considering existing variations between the U.K. and other international guidelines regarding antihypertensive treatment in CKD, continued research is indicated to bridge the gaps between these recommendations and optimise patient outcomes.
ENVIRONMENTAL MELAMINE EXPOSURE AND ADVERSE KIDNEY OUTCOMES IN PATIENTS WITH TYPE 2 DIABETES MELLITUS

Yi-Chun Tsai¹,² and Ming-Tsang Wu³

¹Kaohsiung, Taiwan, Rep. of China, ²Kaohsiung Medical University Hospital, Kaohsiung, Taiwan, Rep. of China and ³Kaohsiung Medical University, Kaohsiung, Taiwan, Rep. of China

Background and Aims: The impact of environmental melamine exposure on kidney outcomes in type 2 diabetes (T2D) remains unclear. The aim of this study is to evaluate the relationship between melamine and adverse kidney progression in T2D population.

Method: This longitudinal study enrolled 561 T2D patients during October 2016 and June 2020 and followed until December 2021. Baseline urinary melamine levels were measured by LC-MS/MS, and average daily intake (ADI) of melamine was estimated. Primary kidney outcomes were defined as doubling of serum creatinine levels or end stage kidney disease (ESKD), and secondary kidney outcomes included rapid decline in kidney function as estimated glomerular filtration rate (eGFR) decline > 5 ml/min/1.73m²/year.

Results: Baseline median urinary corrected melamine levels and estimated DI of melamine were 0.8 μg/mmol and 0.3 μg/kg/day in 561 T2D patients. During 3.7 years of follow-up, urinary corrected melamine level was positively correlated with reaching composite outcomes of either doubling of serum creatinine levels or ESKD and rapid decline in kidney function. Those with the highest quartile of urinary corrected melamine had 2.96-fold risk of composite outcomes of either doubling of serum creatinine levels or ESKD and 2.47-fold risk of eGFR decline > 5 ml/min/1.73m²/year. Estimated ADI of melamine also had significant correlation with adverse kidney outcomes. Furthermore, the positive relationship between melamine exposure and rapid decline in kidney function was only found in T2D patients with male, baseline eGFR ≥ 60 ml/min/1.73m² or glycated hemoglobin ≤ 7%.

Conclusion: Melamine exposure is significantly associated with kidney outcomes in T2D patients, especially in those with male, well sugar control or preserved baseline kidney function.

PREVALENCE, AWARENESS, TREATMENT, AND CONTROL OF HYPERTENSION IN OLDER ADULTS WITH CHRONIC KIDNEY DISEASE: THE IRISH LONGITUDINAL STUDY ON AGEING

Mohammed Alamin¹, Hamidi Miri¹, Mary Byrne², Robert Gilligan³, Leonard Browne¹,², Donal Sexton¹,²,³ and Austin Stack¹,²,⁶

¹University of Limerick, School of Medicine, Limerick, Ireland, ²University of Limerick, Health Research Institute, Limerick, Ireland, ³Trinity College Dublin, School of Medicine, Dublin, Ireland, ⁴Trinity College Dublin, Department of Medical Gerontology, School of Medicine, Dublin, Ireland, ⁵Trinity College Dublin, Trinity Health Kidney Centre, Dublin, Ireland and ⁶University Hospital Limerick, Department of Nephrology, Limerick, Ireland

Background and Aims: Hypertension is a well-known modifiable risk factor for chronic kidney disease (CKD) yet effective management remains a challenge. Data on hypertension awareness, treatment and control among CKD patients in Ireland is limited. Therefore, the objective of this study was to determine the prevalence, extent of awareness, treatment and control of hypertension among older adults with CKD in the Irish population.

Method: We utilised cross sectional data from the first wave of The Irish Longitudinal Study on Ageing (TILDA) conducted between 2009 and 2011. Participants aged 50 years or more with complete measurements on serum creatinine and blood pressure (BP) were included (n = 5,356). CKD was defined as eGFR <60ml/min/1.72m². Hypertension was defined as systolic blood pressure ≥140 mmHg and/or diastolic blood pressure ≥90 mmHg and/or self-reported use of antihypertensive medication. Participants' awareness and treatment of hypertension were defined using self-report and hypertension control was evaluated as systolic/diastolic blood pressure <140/90 mmHg. We determined the weighted prevalence of hypertension, awareness, treatment, and control using sample weights, and multivariable logistic regression explored associations of demographic, clinical and behavioural characteristics with control of hypertension. Associations were expressed using adjusted odds ratios (OR) with 95% confidence intervals (CIs). Analyses were conducted in Stata and R.
Method: There were 639/5,356 participants (13.3% (95% CI: 12.3-14.4)) with CKD. The weighted prevalence of hypertension was significantly higher in participants with CKD than without CKD (81.8% versus 59.8% respectively, P<0.001). Among those with CKD and hypertension, 70.8% (95% CI: 66.5-74.7) were aware of hypertension, and 83.4% (95% CI: 79.9-86.5) were treated with antihypertensive medication. Despite higher levels of awareness and treatment of hypertension in those with CKD, only 50.4% (95% CI 45.4-55.5) of treated subjects had BP <140/90 mmHg. BP control was similarly poor for non-CKD participants at 49.4% (95% CI: 46.9-51.8). The most commonly used medications among treated CKD participants were β-blockers 41.8% (95% CI 36.7-47.1), angiotensin-converting enzyme inhibitors 34.0% (95% CI 29.2-39.2), and angiotensin receptor blockers 33.7% (95% CI: 28.9-38.8). Over half [54.8% (95% CI: 49.5-60.0)] of CKD participants were treated with ≥2 antihypertensive medications. In multivariable analysis, the likelihood of BP control (<140/90 mmHg) was lower for older CKD patients [OR: 0.94 (95% CI: 0.90-0.98) per 1 year increase in age], greater for those on combination therapy [OR: 1.87 (95% CI: 1.13-3.1)] and for those with history of cardiovascular disease [OR: 2.33 (95% CI: 1.43-3.82)].

Conclusion: Despite established evidence that control of hypertension can slow the progression of CKD and reduce cardiovascular complications, our results indicate that the prevalence of hypertension in older adults with CKD is high and the control of hypertension is poor and worsens with advancing age. Approximately, one third of participants with CKD were unaware of their hypertensive status and approximately one fifth of participants were untreated.

WHAT IS IMPORTANT IN PRIMARY CARDIORENAL INTERACTION SYNDROME
Danijela Tasic1, Zorica Dimitrijevic1, Sonja Radenkovic2 and Gordana Kocić3
1University of Niš, Faculty of Medicine, UCC, Clinic of Nephrology, Niš, Serbia, 2University of Niš, Faculty of medicine, Institute of Pachophysiology, Niš, Serbia and 3University of Niš, Faculty of Medicine, Niš, Serbia

Background and Aims: Renal function is important in congestive heart failure syndrome because existing or secondary-induced renal weakness contributes to the worsening and progression of heart failure. Decreased ejection fraction in acute heart failure leads to more acute kidney damage compared to patients with preserved ejection fraction. Also, heart failure with a drop in the ejection fraction of the left ventricle is not a dominant characteristic of patients with cardiorenal syndrome type 2. A significant risk factor in the first type of cardiorenal syndrome is, among others, age and diabetes. The prevalence of heart failure with preserved ejection fraction and increased left ventricular mass is higher in the elderly. The aim of the work is how to differentiate and which factors predispose the occurrence of the first and second types of primary cardiorenal syndrome.

Method: 42 subjects, 24 men and 18 women, with an average age of 70.72±9.26 years, with a diagnosis of worsening heart function that led to kidney dysfunction, were analyzed. The first type of cardiorenal syndrome accounted for 57.14% and the second type of cardiorenal syndrome accounted for 42.86%. The study was designed as a cross-sectional comparative study, and the main criterion for the inclusion of subjects was the existence of a new or previously diagnosed clinically manifest cardiovascular disease. Continuous variables are presented with mean values, standard deviations and medians, and categorical variables with frequencies and percentages. The normality of the distribution of continuous variables was determined by the Shapiro-Wilk test. Depending on the normality of the distribution of continuous variables, the comparison of continuous variables between two groups was performed by the Student’s t-test of unknown samples in the case of normality, or by the Mann-Whitney test in the case that the distribution deviates from normality. Determining the difference in the representation of categorical variable modalities between groups was determined by the chi-squared test. Values of p<0.05 were considered statistically significant.

Results: Based on everything is done, the following was determined as statistically significant: Patients with CRS2 are statistically significantly older than patients with CRS1 (p<0.05, Student’s t-test of independent samples), and they also have a statistically significantly higher value of HDL-C (p<0.05), Patients with diabetes (p = 0.0488) and with sinus rhythm (p = 0.0442) were statistically significantly more represented in patients with CRS1. Patients with CRS1 had statistically significantly higher values of serum urea and serum creatinine compared to patients with CRS2 (p<0.05, Mann Whitney test). In patients with CRS2, the value of AOPP was statistically significantly higher than in patients with CRS1 (p<0.01, Student’s t-test of independent samples).

Conclusion: The results obtained in our study are related to the assessment of the functional state of the heart and kidneys in primary cardiorenal syndrome type one and two in which the main predisposing factors are age, diabetes and reduction of renal function. By correlation analysis in the second type of cardiorenal syndrome, HDL-C particles were significantly elevated. Although the values of nitrogen products were lower in the second type of cardiorenal syndrome, AOPP stood out as statistically significant in the lower functional class.

CLINICAL CHARACTERISTICS AND PRIMARY OUTCOMES OF PATIENTS WITH ANCA-ASSOCIATED VASCULITIS AND CENTRAL DIABETES INSIPIDUS
Xin Chen1, Shuo Zhang1, Peng Xia3, Xiaoxiao Shi3, Wuhai Ting1, Yu-Bing Wen1, Yan Qin1, Xingping Tian1, Huijuan Zhu2 and Limeng Chen1
1Peking Union Medical College Hospital, Nephrology, Dongcheng-qu, P.R. China, 2Peking Union Medical College Hospital, Rheumatology, Dongcheng-qu, P.R. China and 3Peking Union Medical College Hospital, Endocrinology, Dongcheng-qu, P.R. China
**Background and Aims:** Anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV) is characterized by systemic small-vessel vasculitis and may rarely present as central diabetes insipidus (CDI). AAV-associated CDI should be recognized to avoid unnecessary biopsies of the pituitary gland and minimize the risk of irreversible loss of pituitary function. In this study, we aimed to determine the clinical characteristics and prognosis of patients with AAV-associated CDI.

**Method:** This was a nested case-control study where AAV patients with CDI at the Peking Union Medical College Hospital were followed from January 2012 to April 2022. Case-control matching with AAV patients without CDI was performed (1:2), and participants were matched by age, sex, and AAV classification. We collected clinical data every 3–6 months and conducted a literature review using PubMed to identify relevant articles published from 1983–2022.

**Results:** Among 1203 hospitalized AAV patients, 16 patients with CDI were included (1.3%). The average age was 49 years, and men accounted for 56.3%. Granulomatosis with polyangiitis (GPA) accounted for 87.5% of patients. AAV patients with CDI had more ear, nose, and throat (ENT) (81.3%) involvement and less renal impairment than those in the control group (P < 0.05). After a mean follow-up of four years, 50% of patients were in remission, 37.5% relapsed, and 12.5% died. Our literature review suggested that patients in Asian countries tend to be older men and have higher MPO-ANCA positivity than those in European countries. Furthermore, PR3-ANCA positivity may predict disease recurrence.

**Conclusion:** AAV patients with CDI had more ENT involvement and a higher eGFR. MPO-ANCA positivity is more commonly observed in Asian countries than in European countries, and PR3-ANCA positivity may predict recurrence.

**ASSOCIATION OF DEMENTIA AND EXPOSURE OF PROTON PUMP INHIBITORS IN DIABETIC PATIENTS**

Yi-Hsin Chen

Taichung Tzuchi Hospital, Nephrology, Taichung City, Taiwan, Rep. of China

**Background and Aims:** Dementia is characterized by a decline in cognition and an increasing inability to live independently. Proton pump inhibitors (PPI) are commonly used to treat gastric or duodenal ulcers. Recently, concern about the risk of dementia and exposure to PPI was noted. However, no known association has previously been reported in patients with diabetes.

**Method:** We analyzed data from the Taiwan National Health Insurance Research Database between January 1st, 2002 and December 31st, 2013. A total of 526920 diabetic patients were selected as the study cohort. A 1 to 4 propensity score was used for matching.

**Results:** During the follow-up period, 169 (2.2%) patients experienced newly diagnosed dementia compared to 1.7% of the control group. According to univariate analysis, the hazard ratio of dementia when exposed to PPI was 1.98 (p = 0.0007). In multivariate analysis, the hazard ratio of exposure to PPI was 1.11 (p = 0.0008). In the sensitivity test, greater than 180 cDDDs were associated with a hazard ratio of 1.5 (p = 0.0006).

**Conclusion:** The association between PPI use and dementia was significant in diabetic patients. Therefore, PPI use should be cautious in this population. Further study is needed to clarify the mechanism.

**EFFECT ON BLOOD PRESSURE AND CARDIOVASCULAR RISK FACTORS IN PEDIATRIC PATIENTS DURING COVID-19 PANDEMIC CONFINEMENT (COBECOR STUDY)**

Elena Codina Sampera1, Pedro Arango Sancho1, Ana Cristina Aguilar Rodríguez2, Bernat Gómez Herrera1, Marta Jiménez Moreno1, Yolanda Calzáda Baños1, Raquel Jiménez García1, Verónica Coll Brito1, Osmar David González3 and Álvaro Madrid Aris1

1Hospital Sant Joan de Déu, Pediatric Nephrology, Esplugues de Llobregat, Spain, 2Fundació Puigvert, Barcelona, Spain and 3Pontificia Universidad Católica de Chile, Santiago, Chile

**Background and Aims:** Patients monitored in the cardiovascular risk (CVR) consultation usually present overweight/obesity, metabolic syndrome, tendency to hypertension (HTN), poor eating habits and sedentary lifestyle, with great resistance to change, great influence of the environment and, frequently, psychosocial limitations. We asked whether home confinement for COVID-19 (March-May 2020) could have negative effects in relation to CVR in these patients. The main objective of this work is to assess this hypothesis with respect to HTN and the use of antihypertensive drugs in these patients. As a secondary objective, we assessed changes in other parameters: body mass index (BMI), level of physical activity and diet.

**Method:** Retrospective cohort study with review of 738 ambulatory blood pressure monitoring (ABPM) between 2019-2022 obtaining, after applying the exclusion criteria (no overweight/obesity, poor therapeutic compliance, underlying renal pathology or failure to perform two ABPM in the study period), a final cohort of 46 patients divided into two groups (23 each): one group exposed to home confinement (G1) with one ABPM before and after home confinement and another group not exposed to confinement (G2) with two ABPM in different periods between 2021-2022. Blood pressure (BP) percentile values, dipper pattern, variability and blood pressure load, as well as the rest of the CVR parameters were compared in both periods.

**Results:** The mean age was 13 years (13.8 G1/13.2 G2) with a mean time between the 1st and 2nd ABPM of 11 months (11.08 G1/10.95 G2) and a greater reduction in BMI in G2 than in G1 (1.05 G1/1.21 G2). Despite this, the results were not statistically significant. Nor were the results significant in terms of differences in AT or worsening of the dipper pattern (30.4% in G1 and 21.7% in G2). We did observe differences (p < 0.022) in the use of antihypertensive drugs, although contrary to our initial hypothesis, with greater use of drugs in G2.

**Conclusion:** Although the low sample size, the biases inherent in the design and the lack of previous studies make the interpretability and statistical significance of some results difficult, they reinforce that the measures during confinement did not contemplate all spheres of health and the need to implement specific CVR consultations. Obesity and its associated pathologies are an important public health problem that pediatricians have the responsibility to address.

**ULTRASOUND IMAGING PATTERNS OF KIDNEY DISEASE IN PATIENTS WITH METABOLIC SYNDROME**

Rostyslav Bubnov

Clinical Hospital ‘Pheophania’ of State Affairs Department, Ultrasound, Kyiv, Ukraine

**Background and Aims:** Meeting definition of metabolic syndrome (MetS) requires detection of central obesity (increasing waist circumference, WC) plus any two of the other four factors (hyperglycemia, dyslipidemia, cardiovascular disease, hypertension) [1]. Up to date, kidney evaluation is not fully reflected in MetS evaluation. Multiparameter ultrasound (US) can provide accurate information on every MetS sign [2] and for specific detecting type of chronic kidney disease (CKD) [3]. The Aim was to study added diagnostic value of ultrasound diagnosis of chronic kidney disease in patients with MetS for precise diagnosis and patients stratification.

**Method:** We included 48 overweight subjects patients (27–75 years; 25 women) with signs of MetS, BMI > 30, waist circumference (WC) > 110. The control group included 50 healthy individuals (26 women), mean age 43 ± 7 years without clinical, laboratory signs of MetS, nephropathy and liver pathology. All patients underwent general clinical, lab tests; abdominal US including precise multiparameter US of kidneys as in [3] measuring shear wave elastography (SWE), Doppler in parenchyma and vessels. We determined fat accumulations measuring VF and subcutaneous (SF) fat thickness (cm) and areas (cm²) on US.

**Results:** We detected hypertension (in 62%); hypercholesterolemia (in 45%); hyperuricemia (in 28%); hyperglycemia (in 32%); nephropathy (in 37%), portal hypertension (in 32%) in obese individuals (vs controls p < 0.05). In all patients we found increasing of visceral fat and various abnormalities in kidneys on US, we distinguished patterns in according to constituents of MetS by its definition follows:
Diabetic nephropathy included mild decreasing or normal kidneys size, thinning parenchyma, low differentiation, clear smooth margins, Doppler showed mild decreasing velocities, increasing of RI in segmental arteries over 0.7 (Figure 1).

Ischemic pattern associated with advanced atherosclerosis included severe decreasing of size, thinned, hyperechoic parenchyma; decreasing velocities under 25 cm/s., severe increasing of RI over 0.8.

Hypertension associated nephropathy: mild changes in structure, normal velocities, increased RI (Figure 2). Hypertension correlated with levels of RI.

Nephropathy in hyperuricemia and gout: signs as in [3] included thinning, increasing echogenicity of kidney parenchyma (P < 0.05), detection of fibrotic changes and small hyperechoic inclusions, hilly margins, anechoic strips under the capsule, RI increasing in segmental arteries over 0.7.

“Circular pyramids pattern” included hyperechoic circles around pyramids (white pyramids sign, hyperdense renal pyramids sign) with normal size, normal / mild increase of RI. SWE showed increased parenchyma stiffness to 10 ± 1.7 kPa (6–17 kPa) versus 4.2 ± 1.2 kPa (P < .05), showed differences among patterns, highest values were in nephropathy in gout and ischemia.

Conclusion: Multiparameter ultrasound is effective for detecting and distinguishing patterns of kidney disease in MetS provides additional value for differentiation and modification treatment and targeted prevention. Kidney involvement should be considered in management of MetS.
interdialytic interval. The parameters evaluated by the Mobil-o-graph device were peripheral and central systolic (pSBP and cSBP) and diastolic (pDBP and cDBP) blood pressure and pulse wave velocity (PWV). All patients were screened for hydration status with lung ultrasound before entering the study and body weight was actively monitored before each session.

Results: Overall, 29 patients with a mean age of 57.9±14.9 years were included in this prospective interventional study. Body weight did not change significantly between the 3 dialysate concentrations. There was a significant increase of 6 mmHg in the mean pSBP with the change in sodium concentration from 137 to 139 and to 141 meq/l (from 122.7 to 125.6 and to 128.3 mmHg respectively, p = 0.032). Mean cSBP was also significantly increased by 5 mmHg (from 110.3 to 112.6 and to 115.1 mmHg respectively, p = 0.02). Peripheral and central DBP did not change significantly (from 71.4 to 73.2 and to 74.1 mmHg, p = ns and from 73.9 to 74.8 and to 75.3 mmHg, p = ns, respectively), as well as PWV (from 8.4 to 8.2 cm/sec, p = ns).

Conclusion: The increasing sodium concentration in the dialysate causes a significant increase in systolic blood pressure and body weight, without a change in PWV.

#5690
COMBINED USE OF SOLUBLE ST2 AND NT-PROBNP FOR PREDICTING MAJOR ADVERSE CARDIOVASCULAR EVENTS IN TYPE 2 DIABETES AND DIVERSE RENAL FUNCTION

Xabier Irazusta Olloquegui1, Jose Maria Mora Gutierrez2,3, Laura Juliana Castaneda-Infante2, Saioa Echeverria Andueza4, Marina Pascual Icoz1,3, Susanna Ravassa1,3, Agnes Diaz-Dorronsoro1, Maria A Fernandez-Seara5, Francisco Javier Escalada1,4 and Nuria Garcia-Fernandez1,3

Background and Aims: Plasma levels of soluble ST2 protein (sST2), a biomarker associated with fibrosis and inflammation, have been related with an increased risk of adverse events in patients with heart failure (HF) [1,2]; however, data is limited on the prognostic value of sST2 in patients with type 2 diabetes mellitus (T2DM) [3], particularly in association with chronic kidney disease (CKD) [4]. We aimed to evaluate the impact on cardiovascular (CV) prognosis of sST2 in a population of T2DM with diverse renal function.

Method: A prospective observational study was conducted in patients with T2DM. Demographic, clinical and analytical data were collected. The main objective was to analyze a composite of combined CV events (major adverse cardiovascular events; MACE) including: CV death, acute myocardial infarction, stroke, coronary revascularization, hospitalization for heart failure, atrial fibrillation, significant valvular heart disease, and hospitalization for any other CV cause). The levels of sST2 and NT-proBNP were analyzed in association with the primary endpoint, as well as with each event separately by survival analysis (log-rank test).

Results: Ninety-three patients were included with a mean follow-up of 3.5 (3.4-4.2) years. Median sST2 concentrations were 29.8 ng/mL. Table 1 shows the baseline characteristics of patients according to sST2 levels. Univariate analysis showed that higher sST2 levels independently predicted the occurrence of MACE (HR = 2.92; 95% CI: 1.35-6.33) (Figure 1). These results persisted after adjusting for age, sex, and glomerular filtration rate. In addition, a significant interaction was found between sST2 and NT-proBNP, showing a

Figure 1: Panel (A): Combined target results of MACE events in patients with sST2 above the median (sST2 ≥ 29.8 ng/mL) (red line), compared with patients with sST2 below the median (blue line). Panel (B): Combined target results of MACE events in patients with NT-proBNP and sST2 below their medians (blue line), patients with only one of the parameters above the median (red line), and patients with both biomarkers above their medians (green line).
significant relationship between the combination of both biomarkers and the main event (Figure 1).

Conclusion: Elevated ST2 levels are associated with the occurrence of long-term major cardiovascular events in patients with T2DM, independently of renal function. These findings could allow stratification of patients with T2DM according to their cardiovascular risk in order to develop therapeutic strategies based on precision medicine.

ACCURACY OF FIXED 24-H AMBULATORY BLOOD PRESSURE RECORDINGS FOR DIAGNOSING HIGH 48-H AMBULATORY BLOOD PRESSURE IN HEMODIALYSIS PATIENTS

Marieta Theodorakopoulou1, Foteini Iatridi1, Eva Pella1, Antonios Karpetas2, Areti Georgiou1, Erasmia Sampani1, Eleni Karkamani1, Alexandros Tsiotouridis1, Aikaterini Papagianni1 and Pantelis Sarafidis1

1Aristotle University of Thessaloniki, Department of Nephrology, Hippokration Hospital, Greece and 2Therapeutiki Hemodialysis Unit, Θεσσαλονίκη, Greece.

Background and Aims: Hypertension is highly prevalent in hemodialysis patients. Ambulatory-BP-monitoring (ABPM) during the 44-h interdialytic interval is recommended for hypertension diagnosis and management in these subjects. This study assessed the diagnostic accuracy of fixed 24-h ABPM recordings with 44-h BP in hemodialysis patients.

Method: 242 Greek hemodialysis patients that underwent valid 48-h ABPM (Mobil-O-Graph NG device) were included in the analysis. We used 44-h BP used as reference method and tested the accuracy of the following BP metrics: 1st 24-h without HD period (20h-1st), 1st 24-h including HD period (24h-1st) and 2nd 24-h (24h-2nd).

Results: All studied metrics showed strong correlations with 44-h SBP/DBP (20h-1st: r = 0.973/0.978, 24h-1st: r = 0.964/0.972 and 24h-2nd: r = 0.978/0.977, respectively). In Bland-Altman analysis, small between-method differences (−1.70, −1.19 and +1.45 mmHg) with good 95% limits-of-agreement ([−10.83 to 7.43], [−11.12 to 8.74] and [−6.33 to 9.23] mmHg, respectively) for 20h-1st, 24h-1st and 24h-2nd SBP were observed. The sensitivity/specificity and κ-statistic for diagnosing 44-h SBP ≥ 130 mmHg were high for 20h-1st SBP (87.2%/96.0%, κ-statistic = 0.817), 24h-1st SBP (88.7%/96.0%, κ-statistic = 0.833) and 24h-2nd SBP (95.0%/88.1%, κ-statistic = 0.837). Similar observations were made for DBP In ROC-analyses, all studied BP metrics showed excellent performance with high Area-Under-the-Curve values (20h-1st: 0.983/0.992, 24h-1st: 0.984/0.987 and 24h-2nd: 0.982/0.989 for SBP/DBP respectively).

Conclusion: Fixed 24-h ABPM recordings during either the first or the second day of interdialytic interval have high accuracy and strong agreement with 44-h BP in hemodialysis patients. Thus, ABPM recordings of either the first or the second interdialytic day could be used for hypertension diagnosis and management in these subjects.

COMPLIANCE OF DIABETIC MONITORING IN PATIENTS WITH END-STAGE RENAL DISEASE ON MAINTENANCE HEMODIALYSIS

Alwyn Yung Zhuang Choo1,2, Thatoe Aung3 and Vivian Yiu4,5

1United Kingdom, 2Norfolk & Norwich University Hospital, Norwich, United Kingdom, 3Eastbourne District General Hospital, Eastbourne, United Kingdom, 4Bury St. Edmonds, United Kingdom and 5West Suffolk Hospital, Bury St Edmunds, United Kingdom.

Background and Aims: Diabetic nephropathy is a major cause of end-stage kidney disease (ESKD) in the UK, accounting for nearly 30% of patients requiring dialysis and in some units over 40% of the people on dialysis have diabetes. The national reviewing and benchmarking committee (GRFt NHS) had highlighted the disjointed and variable care received by these patients, with increasing risk of complications including blindness, foot ulcers and amputations from suboptimal care. Increased monitoring is shown to be cost-effective and co-ordination of a multi-disciplinary team focus can reduce complications especially lower limb amputation rates. Hence, we aimed to review the quality of care on our setting and compare it to national recommendations.

Method: We performed a cross-sectional review on patients with diabetes on haemodialysis in the satellite unit at a district general hospital to assess compliance with the Joint British Diabetes Societies (JBDS) and the UK Kidney Association (UKKA) recommendations on management of adults with diabetes. Subsequently we introduced monitoring protocols for the relevant key areas of diabetes monitoring (pre and post-dialysis glucose checks, Hba1c checks, check boxes for once weekly feet inspections, criteria for inpatient podiatry review), highlighted potential complications including hypoglycaemia, re-emphasised the importance of adequate documentation to allied healthcare teams, and updated the haemodialysis monitoring sheets. We worked with the unit manager to highlight the rationale for monitoring and provided brief education on complications to the team, and over repeated visits, gained the confidence and support of staff for the changes suggested despite an increased workload.

Results: We reviewed data from January to April 2021 followed by re-evaluation 12 months later after implementation of changes. Data for 25 patients were reviewed and re-assessed after a year. 7 patients passed away during this period. Initial review recognised the lack of awareness of good practice management of diabetic patients in the haemodialysis unit. Most patients have type 2 diabetes which carries a higher risk of ESKD. After a year of change in protocols there were significant improvements in monitoring parameters, with greatest improvements seen in glucose monitoring and routine feet inspections.

Conclusion: The review was based on care standards that included diabetes parameters as part of the recommended national care processes, and individualised treatment approach. The aims included were performing annual reviews, adequate glucose monitoring and rational glycaemic targets, and earlier targeted involvement of the diabetes specialist team. There was improvement in most of the monitoring parameters and clearer documentations from allied healthcare teams. Implementation of recommendations was initially challenging due to the COVID-19 pandemic and staff workload on the unit however with persistence we were able to obtain co-operation from the team. As expected, patients on insulin/sulphonylureas (SUs) had proper blood glucose monitoring methods. Most were on insulin, and the remaining were on SU and DPP-IV inhibitor, and those with Hba1c <58 mmol/mol declined. One-third of these patients used flash glucose monitoring and with increasing recognition and recommendation by the NHS hopefully more patients will benefit from this. This audit showed that simple interventions such as staff engagement and education can improve care and monitoring of patients in this population. With recovery of service provisions, more interventions can be put in place. Following this, we can reaudit amputation rates and gather patient feedback, plan interventions with the community team, and encourage involvement from general practitioners and their trainees to deliver better care to these patients. Hence, we emphasise the importance of clear protocols for the management and monitoring of each patient with diabetes mellitus in haemodialysis units to ensure care standards are met.
CLINICAL PROFILE OF PATIENTS WITH DIABETIC KIDNEY DISEASE ATTENDING NEPHROLOGY CLINICS IN A LOW-MIDDLE INCOME COUNTRY

Sonia Yaqub1, Marwah Saeed2, Safia Awan2 and Sanam Bano2

1Aga Khan University Hospital (AKUH), Medicine, Karachi, Pakistan and
2Aga Khan University Hospital (AKUH), Karachi, Pakistan

Background and Aims: Chronic kidney disease secondary to diabetes is a significant contributor to the global burden of disease, both financially and through a marked deterioration in the quality of life. Diabetic kidney disease (DKD) increases the likelihood of adverse outcomes such as infirmity, cardiovascular events, progressive multi-organ damage, impaired quality of life and reduced life expectancy. Pakistan, a low-middle income country, is ranked among the top 10 countries for absolute diabetes prevalence. Over 19 million Pakistani adults have diabetes, which amounts to 17.1% of the adult population in the country. There is a dearth of literature examining the quality of care of diabetic kidney disease (DKD) patients in Pakistan. The aim of the current study is to evaluate the clinical profile and the quality of care delivered to patients with DKD attending nephrology clinics at a large tertiary care hospital in Karachi, Pakistan.

Method: It was a cross-sectional observational study at Aga Khan University Hospital (AKUH), a private tertiary-care facility located in Karachi, Pakistan. The data used in the study was acquired from the Diabetic Kidney Disease outpatient-database, a registry of patients managed by AKUH. It was used to identify a cohort of patients, with DKD presenting to the nephrology clinic at AKUH from December 2018-January 2021 (n = 553).

Results: Mean age of the study participants was 61.7 ± 11.0 years and 60.9% of the study participants were male. 80.5% (n = 445) were non-smokers and over three-quarters (n = 400) had a body mass index (BMI) > 25 which according to the Asian-Pacific BMI cut-offs classified them as obese. These patients had been living with diabetes for an average of 15 years (median IQR = 10-21) and 99% had type 2 diabetes mellitus. A total of 519 study participants (93.9%) had hypertension while 34.2% and 30.9% had dyslipidemia and ischemic heart disease (IHD), respectively. Almost two third of the participants (68.4%) had advanced CKD (stages 3b, 4 and 5) at the time of presentation. Less than half of the study population (43.6%) had HbA1c < 7.0 percentage and only 34.9% attained systolic blood pressure (BP) target <130mm Hg while optimal diastolic BP (<80 mmHg) targets were achieved in 72.7%. Almost 70% of the study population were on insulin while 49.7% were receiving oral anti-diabetics. The most prescribed oral anti-diabetic was DPP4 followed by metformin and two thirds were on statins. Calcium channel blockers and beta-blockers were the most used antihypertensive drugs 53.5% and 52.6% respectively; half of the population was on diuretics, while 47.4% were taking Renin-angiotensin system (RAAS) blockers. Those who had eGFR > 60, only 60% of them were receiving RAAS blockade therapy. Women were more likely to be obese and to have higher systolic BP compared to men. Diastolic BP and HbA1c were similar in men and women. The use of statins was higher in men and use of calcium channel blockers and RAAS blockers was significantly higher in women.

Conclusion: The basis for DKD management is multifactorial risk factor reduction which is achieved by optimizing care through modifiable risk factors. In our study we identified potential gaps in the quality of care related to risk factor control, optimal glycemic and/or blood pressure targets and pharmacotherapy to delay the progression of DKD and minimize cardiovascular events. This highlights a major treatment gap in DKD prevention and management calling for greater quality improvement effort in Pakistan, which now has the third highest number of people living with diabetes in the world.
Background and Aims: Hypertension and type 2 diabetes mellitus (T2DM) are important, intertwined issues in public health. People with both conditions face significantly elevated risks of complications, particularly albuminuria, which is an independent risk factor for cardiovascular (CV) events, kidney failure and all-cause mortality, and thus deserves more attention among physicians and patients. The purpose of this study is to describe the development of recommendations for the management of hypertension and T2DM by a multidisciplinary expert panel.

Method: The panel included eight specialists (three cardiologists, three endocrinologists and two nephrologists) experienced treating patients with T2DM. The panel followed an evidence-based, multidisciplinary approach to synthesise evidence from the literature, including randomised controlled clinical trials, large observational studies and expert consultations. The final recommendations were agreed upon by all panel members through a series of consensus meetings.

Results: The final recommendations for the management of hypertension and T2DM were divided into five sections: diagnostic and classification, treatment, monitoring, patient education and lifestyle modifications. The recommendations were designed to be applicable to all patients with hypertension and T2DM, regardless of age, gender or comorbidities. Key recommendations included the importance of early detection and aggressive management of hypertension and T2DM, the use of evidence-based antihypertensive and antihyperglycaemic therapies, regular monitoring of blood pressure and glycaemic control, patient education and lifestyle modifications, and the integration of comprehensive care for patients with hypertension and T2DM.

Conclusion: The consensus recommendations developed by this multidisciplinary expert panel provide a comprehensive framework for the management of hypertension and T2DM in patients with these conditions. The recommendations are designed to be adaptable to the specific needs of individual patients, taking into account their age, gender, comorbidities and preferences. The recommendations are intended to improve the outcomes of patients with hypertension and T2DM, reduce the risk of complications and improve the quality of life for these patients.
hypertension or T2DM. The panel reviewed clinical trials, meta-analyses, observational studies and clinical guidelines that were obtained by searching PubMed for the publication period from January 2015 to June 2021, to address five discussion areas: (i) blood pressure (BP) targets based on CV/renal benefits; (ii) management of isolated systolic or diastolic hypertension; (iii) roles of angiotensin II receptor blockers (ARBs); (iv) implications of albuminuria for CV/renal events and treatment choices; and (v) roles and tools of screening for microalbuminuria. The panel held three virtual meetings using a modified Delphi method to discuss the literature and their experience regarding the discussion areas. After each meeting, consensus statements were derived and anonymously voted on by every panelist. A consensus statement was accepted only if ≥ 80% of the panelists selected ‘accept completely’ or ‘accept with some reservation’.

Results: A total of 17 consensus statements were formulated.

Conclusion: The key messages include: (i) home BP is considered as important as office BP in treatment decision-making; (ii) in patients with T2DM and hypertension on antihypertensive drug treatment, the targets important as office BP in treatment decision-making; (ii) in patients with T2DM and hypertension, the targets should be < 130/80 mmHg for office BP and < 125/75 mmHg for home BP; (iii) albuminuria is an important therapeutic goal and should be screened for regularly in people with T2DM or hypertension; and (iv) an ARB with proven cardioprotective and renoprotective effects is the preferred drug treatment for patients with T2DM and hypertension.

#4540
LONG-TERM OUTCOMES AFTER RENAL DENERVATION: A FOLLOW-UP OF 5 YEARS

Maria Inês Roxo¹, Andreia Carnevale¹, Ana Rita Calça¹, Ana Rita Martins¹, Pedro Gonçalves², Manuel Almeida², Augusta Gaspar¹ and Patricia Branco²

¹Hospital Santa Cruz, Nephrology, Carnaxide, Portugal and ²Hospital Santa Cruz, Cardiology, Carnaxide, Portugal

Background and Aims: Arterial hypertension is a significant cause of cardiovascular morbimortality worldwide. Adequate blood pressure control constitutes a crucial tool to prevent the enduring end-organ damage inflicted by hypertension and, consequently, its high burden of disease. Resistant hypertension may be particularly challenging to address: in this field, denervation of the renal sympathetic nerves is developing as a promising
despite controversial therapy. Our goal was to study long-term outcomes in a cohort of patients with resistant hypertension who underwent renal denervation between July 2011 and July 2022. All patients routinely underwent blood and urine testing, 24-hour ambulatory blood pressure monitoring (ABPM) and echocardiographic evaluation every 6 to 12 months after the procedure. We collected several demographic, clinical and laboratory variables, and analysed outcomes at 5 years of follow-up using SPSS software.

Results: 78 patients were submitted to renal denervation in our centre, 53% of which (n = 41) were male. There were no reported complications related to the procedure. At 5 years of follow-up, there were different types of responders. In ABPM, 61% of the patients showed a decrease in mean systolic blood pressure (SBP), with a median reduction of 16 mmHg (IQR 16.5). In 46% of patients, there was a reduction in albumin/creatinine ratio (ACR), with a median decrease of 17.63 mg/g (IQR 120.67). Before renal denervation, 30 patients (38.5%) had an ACR above 30 mg/g, while after 5 years the number of patients with ACR in this range was 21 (26.9%). In echocardiographic evaluation, 70% of the patients evidenced a decrease in left ventricular mass index (LVMI) with a median reduction of 20 g/m² (IQR 41). These results are summarised in Figure 1. In total, 70% of the patients were considered responders to renal denervation, either through a reduction in mean SBP in ABPM, in LVMI, in ACR or simultaneously in all three variables. Additionally, the reduction in mean SBP in ABPM, LVMI and ACR proved to be independent variables, both in Spearman tests and binary logistic linear regression (nonsignificant p-values). 77% of the patients were prescribed less antihypertensive drugs after follow-up, with a median reduction of 2 drugs (IQR 2).

Conclusion: Our study identified a significant percentage of responders to renal denervation, evidenced by an improvement in one or more variables associated with blood pressure control and hypertension-mediated end-organ damage, without any safety issues to report. It is also important to emphasize that the observed reduction in ACR and LVMI was independent of the reduction in SBP. This finding suggests that renal denervation might have a direct effect on albuminuria and left ventricular hypertrophy, instead of solely as an indirect result of the control of blood pressure. Hence, while further studies are necessary to support this evidence, the results nevertheless raise hope for the therapeutic potential of renal denervation in patients with resistant hypertension.

Figure 1: Descriptive analysis of the reduction in mSBP in ABPM, RAC and LVMI in responders, before DRSN and 5 years after the procedure (ACR: albumin/creatinine ratio; DRSN: denervation of the renal sympathetic nerves; IQR: interquartile range; LVMI: left ventricular mass index; mSBP in ABPM: mean systolic blood pressure in 24-hour ambulatory blood pressure monitoring).
MITOCHONDRIAL DNA Deregulated Pattern Parallels Inflammation in Early Diabetic Kidney Disease of Type 2 Diabetes Mellitus Patients

Background and Aims: Mitochondrial DNA (mtDNA) abnormalities, as well as complex inflammatory processes involved in the pathogenesis of DKD may be detected early in the course of DKD. The aim of the study was to evaluate a potential relation of mtDNA modifications in blood and urine with podocyte injury and proximal tubule (PT) dysfunction in early DKD of type 2 diabetes mellitus (DM) patients. The hypothesis according to which mtDNA changes may be related to a specific inflammatory response in normoalbuminuric DKD of type 2 DM patients was also questioned.

Method: A total of 150 patients [52 patients with normoalbuminuria, 48 patients with microalbuminuria, and 50 patients with macroalbuminuria] and 30 age- and gender-matched healthy controls were enrolled in this case series study. All patients were assessed concerning urinary albumin/creatinine ratio (UACR), biomarkers of podocyte damage (synaptopodin, podocylaxyin) and of PT dysfunction (kidney injury molecule-1-KIM-1, N-acetyl-D-glucosaminidase-NAG), serum and urinary interleukins (IL-17A, IL-18, IL-10), and eGFR (creatinine-cystatin C). MtDNA-CN and nuclear DNA (nDNA) was quantified in peripheral blood and urine by qRT-PCR (ABI 7900 HT–Applied Biosystem). TaqMan assays were utilized for the assessment of cytochrome b (CYTB), gene subunit 2 of NADH dehydrogenase (ND2), and of beta 2 microglobulin gene nuclear (B2M). mtDNA-CN was defined as the ratio of the number of mtDNA/nDNA copies, through analysis of the CYTB/B2M and ND2/B2M ratio. DNA standards were created by plasmidial cloning vectors. Cloning was verified by PCR sequencing and validation.

Results: Serum mtDNA was decreased, while urinary mtDNA was increased in all study groups as compared to healthy controls. In univariable linear analysis, serum mtDNA correlated directly with UACR, synaptopodin, podocylaxyin, KIM-1, and urinary KIM-1, and urinary NAG. Also, serum mtDNA correlated negatively with serum IL-17A and urinary IL-17A, and with serum IL-18 and urinary IL-18, and directly with serum IL-10 and urinary IL-10. Urinary mtDNA correlated directly with UACR, synaptopodin, IL-17A, and IL-18, and showed an inverse correlation with IL-10, and eGFR. Multivariable linear analysis provided models in which serum mtDNA correlated directly with IL-10, and indirectly with UACR, IL-17A, and KIM-1 (R2 = 0.626; p = 0.0001). Urinary mtDNA correlated directly with UACR, podocalyxin, IL-18, and NAG, and negatively with IL-10 and eGFR (R2 = 0.631; p = 0.0001). This data suggests that increased urinary mtDNA levels may be attributed to increased filtration of circulating DNA and that this may derive from filtered and circulating mtDNA due to lesions to the glomerular and tubular structures. The correlations of mtDNA with proinflammatory cytokines IL-17A and IL-18, as well as with the anti-inflammatory cytokine IL-10 could explain the association of these cytokines with mtDNA variations and with the expression of podocyte damage and PT dysfunction biomarkers in all studied groups, even in normoalbuminuric type 2 DM patients.

Conclusion: MtDNA abnormalities and inflammatory processes occur early in the course of type 2 DM. MtDNA displays a specific profile in relation to inflammation both at podocyte and tubular level in normoalbuminuric patients with type 2 DM. These observations are independent of renal function decline.

BLOOD PRESSURE RESPONSE TO A LOW SODIUM DIET IN NORMOTENSIVE SUBJECTS

Fernando Margulies1, Roberto Sabbatidio1, Verónica Goígli2, Carlos Cuenas3, Claudia Castro4, Verónica Aguirrezaabal4, Miriam Martínez5 and Ruben Schiavelli6

1 Hospital General de Aguadú Dr. Argerich, Trasplante Renal y Nefrología, Buenos Aires, Argentina, 2 Hospital General de Aguadú Dr. Argerich, Laboratorio Central, Buenos Aires, Argentina and 3 Hospital General de Aguadú Dr. Argerich, Nutrición, Buenos Aires, Argentina

Background and Aims: The term salt sensitivity (SS) has been used to show an increase in BP in response to saline overload in both normotensive and hypertensive patients. Age, sex, and obesity have been proposed as predisposing factors. The objective of our work was to evaluate the response of office BP (OBP) and ambulatory BP (ABP) to changes in salt intake in healthy normotensive subjects.

Method: We analyzed 193 subjects who participated in the evaluation as potential kidney donors; none had a history of hypertension, diabetes, renal or cardiovascular disease. They received two consecutive standardized diets, one with 300 mEq and the other with 30 mEq of Na+ /day. On the last day of each diet, a 24-h urine collection was obtained and an ambulatory BP monitor was placed for 24 h in the non-dominant arm, following recording of OBP. Data were expressed as mean and standard deviation (SD). Student’s test and one-way ANOVA were used to compare means, values of p < 0.05 were considered statistically significant differences.

Results: In the study group there were 120 females (62%) and 71 were salt sensitive (SS) (37%). The mean age was 46.9 ± 10 years (20 – 72) without significant gender differences (F = 46.7 ± 10 vs M = 47.3 ± 9 p = 0.704). The group was salt sensitive (SS) and significantly higher than the salt resistant (SR) (49.8 ± 9 vs 45.3 ± 10 p = 0.002). BMI was found to be increased (27.7 ± 4) without significant gender or incidence of SS differences. We found no association between gender and SS (p = 0.509). After the high sodium and before low sodium diets, the mean difference in urine Na+ excretion was 165.2 ± 83 mEq/24h, significantly higher among men than women (201.6 ± 84 vs 142.3 ± 75 p = 0.0001). There were no differences based on SS. We did not find significant gender differences in the variation of OBP or ABP, with the changes in the diet. The mean reduction of systolic pressure OBP for the group was 6.13 ± 10 and of diastolic pressure OBP 0.35 ± 5 mmHg. In separate analysis, systolic and diastolic OBP drops were significantly higher in the SS than in the SR (9.69 ± 12 vs 2.57 ± 8 and 2.24 ± 7 vs – 0.95 ± 5 mmHg respectively, p = 0.001). The average reduction in systolic ABP was 7.13 ± 8 and in diastolic ABP 3.33 ± 5 mmHg. In separate group analysis we also observed a significantly greater reduction in SS than in SR (12.83 ± 7 vs 1.8 ± 5 and 6.56 ± 5 vs 0.12 ± 3 mmHg respectively, p = 0.001).

Conclusion: In our study group, the reduction of both OBP and ABP following a low sodium diet in normotensive subjects depends on salt sensitivity and is independent of gender and body weight.
A DEEP LEARNING APPROACH TO PERSONALISED ANTI-HYPERTENSIVE MEDICATION TITRATION

Conor Judge1, Pavel Roshanov2, Martin O’Donnell1 and Bryan Tripp3

1University of Galway, School of Medicine, Galway, Ireland, 2Western University, Medicine, London, Canada and 3University of Waterloo, Waterloo, Canada

Background and Aims: Hypertension is the number one risk factor for premature death worldwide. Artificial Intelligence (AI) Clinical Decision Support Systems are an important next step for hypertension management but require rigorous evaluation before assimilation into routine clinical practice. Our aim is to develop and evaluate an AI clinical decision support tool for hypertension management trained on randomised clinical trial data.

Method: The Systolic Blood Pressure Intervention Trial (SPRINT) trial showed that intensive BP control to SBP <120 mm Hg results in significant cardiovascular benefit in high-risk patients with hypertension compared with routine BP control to <140 mm Hg. We trained a feed-forward neural network using Keras and Tensorflow for R and data from 9361 persons in the SPRINT randomized clinical trial to predict the probability of increase, reduce or no-change in total number of anti-hypertensive medications at each visit. The network is designed to model SPRINT investigator deviations from the protocol. Six baseline patient variables (age, sex, race, aspirin use, eGFR, group assignment (intensive or standard)), two visit patient variables (Systolic and Diastolic Blood Pressure), and two previous visit variables (Systolic and Diastolic Blood Pressure) were inputted into the model after data normalisation and centering. Hyperparameters were tuned using a grid search method. We conducted internal validation using a 20% validation set. Clinical validation was performed using an unseen test set of typical hypertension scenarios (n = 50). An R Shiny app was developed to enter new patient information and display a sensitivity analysis of probabilities calculated after changing each baseline variable by plus and minus 10 (Figure 1). To avoid poor performance on new out of distribution cases we tested five methods for Out of Distribution (OOD) detector, 1. Autoencoders, 2. Normalizing flow, 3. Local Outlier Factor (LOF), 4. Probabilistic Principal Component Analysis (PPCA) and Kernel Density Estimation (KDE).

Results: The accuracy was 76.7% on the validation dataset after 1000 Epochs. Clinical validation revealed suboptimal performance for unseen Out of Distribution data (e.g. recommending reduction of medication when SBP > 160 and number of medications was zero). This poor performance on OOD samples prompted the creation of an OOD detector to use in series with the AI Decision Support System for Hypertension. The AUROCs were 0.77 for AE, 0.96 for Normalizing Flow, 0.82 for LOF, 0.88 for PPCA and 0.96 for the Kernel Density Estimation.

Conclusion: Artificial Intelligence (AI) Clinical Decision Support Systems for Hypertension are feasible and an important next step for hypertension management but generalisability and safety require rigorous evaluation before assimilation into routine clinical practice.

STATIN INITIATION AND RISK OF INCIDENT KIDNEY DISEASE IN PATIENTS WITH DIABETES

Shiyu Zhou, Sheng Nie and Xu Xin

Guangzhou, P.R. China

Background and Aims: The role of statin therapy in the development of kidney disease in patients with type 2 diabetes mellitus (T2DM) remains uncertain. We aim to determine the relationships between statin initiation and kidney outcomes in patients with T2DM.

Method: Using deidentified electronic health record data and new-user design, we conducted a nationwide retrospective cohort of patients with T2DM aged 40 years or older across China. The study outcomes included the development of diabetic kidney disease (DKD) and a sustained ≥40% decline in estimated glomerular filtration rate (eGFR). Cox proportional hazards regression was used to evaluate the relationships between statin initiation and kidney outcomes. Analyses were conducted using propensity overlap weighting to balance the characteristics.

Results: Among 7272 statin initiators and 12 586 noninitiators in the weighted cohort, statin initiation was associated with lower risks of incident DKD (hazard ratio [HR], 0.72; 95% confidence interval [CI] 0.62-0.83), new-onset eGFR <60 ml/min/1.73 m² (HR 0.63, 95% CI 0.50-0.79), new-onset proteinuria (HR, 0.70; 95% CI 0.59-0.84) and kidney function decline (HR 0.60, 95% CI 0.44-0.81). Among statin initiators, intensive control of LDL-C (<1.8 mmol/L) had a lower risk of incident DKD (HR 0.51, 95% CI 0.32-0.81) than that in non-control group (LDL-C ≥ 3.4 mmol/L). Similar results were obtained for participants with differing patterns of dyslipidemia, those using different statins, and after stratification according to the characteristics of the participants.

Conclusion: Statin initiation is significantly associated with a lower risk of kidney disease development in patients with diabetes. This renoprotective effect was more prominent in patients with intensive control of LDL-C.

Figure 1: An R Shiny application for inputting data into the AI decision support tool. In sensitivity analysis, red bar represents probability of an increase in antihypertensive medications, green bar represents probability of no change in antihypertensive medications and blue bar represents probability of decrease in antihypertensive medications.
Figure 1: Statin initiation and weighted cumulative incidence of kidney outcomes in patients with T2DM DKD: diabetic kidney disease, eGFR: estimated glomerular filtration rate.

Figure 2: Adjusted hazard ratio of statin initiation associated with kidney outcomes among the total populations and patients with or without dyslipidemia.

Background and Aims: Diabetes mellitus (DM) is one of the main causes of chronic kidney disease (CKD) and the need for renal replacement therapy. New antidiabetic drugs such as glucagon-like peptide 1 receptor analogues (aGLP1) improve glycemic control and cardiovascular risk and promote weight loss. Our main objective was to analyze the efficacy and safety of aGLP1 agonists in patients with advanced chronic kidney disease (ACKD).

Method: Prospective cohort study of CKD (estimated glomerular filtration rate (eGFR) ≤ 30 ml/min) and DM2 patients who started treatment with aGLP1 between April 2018 and November 2022. We analyzed clinical and demographic variables. We collected aGLP1 type and dose, eGFR and weight at baseline and after 6 and 12 months of treatment. We analyzed glycemic and lipid control and blood pressure (BP). We documented adverse effects. Descriptive analysis was performed and we compared eGFR before and after aGLP1 initiation.

Results: During the period 36 patients with ACKD started treatment with aGLP1 in our center, 30 with a minimum follow-up of 6 months. 66.7% were male and the mean age was 67. 88.9% were hypertensive and 91.7% dyslipidemic. 33.3% had a history of ischemic heart disease, 11.1% heart failure, 41.7% peripheral arterial disease and 8.3% stroke. The mean eGFR at drug initiation was 20.7 mL/min. The most frequent cause of CKD was diabetic nephropathy (66.7%) followed by glomerulonephritis (11.1%). Mean weight was 92.7 ± 9.7 kg and BMI 33.15 ± 3.2 kg/m2. The most prescribed aGLP1 was Semaglutide (83.4%) followed by Liraglutide (13.9%) and Dulaglutide (2.8%). Maximum drug dose was reached in 69.4% of patients. After initiation, eGFR remained stable at 6 months and 1 year (p = .424). We observed a 12% reduction in weight at one year after treatment (94Kg vs 83Kg; p < .001). We found no differences in glycosylated hemoglobin, lipid control and BP at 6th month and first year. Two patients suffered gastrointestinal adverse effects and one discontinued the drug because of this. One patient died during follow-up of independent cause.

Conclusion: aGLP1 in patients with ACKD are safe. Adverse effects do not occur more frequently than in the non-CKD population. In addition to improving cardiovascular risk of patients, they can produce a weight loss that can independently help patients to be included in the waiting list for renal transplantation.

SGLT2-Inhibition Improves Vascular Function in Type 2 Diabetes: A Double Blind, Randomized, Placebo Controlled Crossover Trial

Didde Kidmose Kristensen1, Steffen Flindt Nielsen1, Niels Henrik Buus2, Camilla Duus1, Frederik Mårup2, Jesper Bech1 and Frank Mose1

1Goedstrup Regional Hospital, University Clinic in Nephrology and Hypertension, Herning, Denmark and 2Aarhus University Hospital, Department of Nephrology, Århus N, Denmark

Background and Aims: Sodium glucose cotransporter 2 inhibitors (SGLT2i) reduce cardiovascular events and protects kidney function in type 2 diabetes (DM2) patients. These benefits may partly be related to improvement of vascular function. In this study we examined the effects of SGLT2i treatment on vasodilatory capacity in patients with DM2.

Method: Using a double-blind, randomized, placebo-controlled cross-over study design, we included 15 patients with DM2 and preserved kidney function (eGFR > 60 ml/min/1.73 m²). Each participant received four weeks of SGLT2i treatment (empagliflozin 10 mg once daily) or matching placebo. After a two-week wash-out period, each participant was cross over to four weeks of the opposite treatment. At the end of each treatment period, vascular function was evaluated by venous occlusion plethysmography. Forearm blood flow (FBF) was measured during intra-arterial infusion of increasing concentrations of acetylcholine (ACh) and sodium nitroprusside (SNP), assessing endothelium-dependent and independent vasodilation, respectively. Repeated measures two-way ANOVA was performed to compare absolute FBF between groups.

Results: 11/15 (73%) of participants were male. Mean age was 68 ± 9 (SD) years (range 49-82), eGFR was 81 ± 10 ml/min/1.73 m² and duration of diabetes was 15.8 ± 9 years. 11/15 (73%) had hypertension and 9/15 (60%) received treatment with an ACE-inhibitor or Angiotensin-II blocker. 4/15 (27%) had cardiovascular disease. The median albumin-to-creatinine ratio was 29 mg/g (range: 4-1293). Both ACh and SNP dose-dependently increased FBF (Figure 1 and 2). FBF during SNP infusion was significantly higher during empagliflozin treatment as compared to placebo (p = 0.004), whereas there was no difference between empagliflozin and placebo in FBF during ACh infusion (P = 0.399).

Conclusion: Empagliflozin improves endothelium-independent vasodilata-

tion in patients with DM2, whereas no changes could be observed in endothelium-dependent vasodilation. These results suggest that SGLT2i positively affects vascular function and that the effect is not related to nitric oxide from the endothelium.
EFFECTS OF SGLT-2 INHIBITORS VERSUS DPP-4 INHIBITORS ON ANEMIA IN PATIENTS WITH TYPE 2 DIABETES

Ai-Yu Yang¹ and Hung-Chun Chen²

¹Department of Pharmacy, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan, Rep. of China and ²Division of Nephrology, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, and Faculty of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan, Rep. of China

Background and Aims: The number of people suffering from diabetes has exceeded 400 million worldwide. The incidence of anemia in type 2 diabetes mellitus (T2D) patients is about twice that of non-diabetic patients. Moreover, patients with T2D who have chronic kidney disease are at higher risk of developing anemia and it also occurs earlier. Therefore it is worth investigating the problem of anemia in T2D patients. This study was conducted to compare the effects of the new oral hypoglycemic agents (sodium-glucose cotransporter-2 inhibitors, SGLT-2i and dipeptidyl peptidase-4 inhibitors, DPP-4i) on anemia in patients with T2D.

Method: This study was designed as a retrospective cohort study and analyzed using the Kaohsiung Medical University Hospital Research Database (KMUHRD). Study inclusion criteria: (1) patients start using SGLT-2i or DPP-4i from January 1, 2015 to December 31, 2020 (first prescription is defined as not used within 180 days prior to the activation date, and cases are screened from the year prior to the starting intake date), and (2) patients with T2D who meet the diagnosis of anemia (according to the World Health Organization definition of hemoglobin <13 g/ dL in men and <12 g/ dL in women) at the time of initial dosing. Patients without hemoglobin data within 180 days before and after treatment were excluded. The outcome will evaluate the effect of SGLT-2i and DPP-4i on erythropoietic parameters including erythrocyte, reticulocyte count, hemoglobin, and hematocrit.

Results: In total 4,555 patients were enrolled in this study. Of these patients, 4,251 were treated with DPP-4i and 304 with SGLT-2i. Using propensity score matching, 303 patients each from the DPP-4i and SGLT-2i groups were selected based on patient characteristics. There were no difference in hemoglobin values (Median: 11.30 vs. 11.20 g/ dL, P = 0.328) and renal function (expressed as...
eGFR, 83.30 vs. 81.84 mL/min, P = 0.255) between the DPP-4i and SGLT-2i groups before treatment. After six months of follow-up, only the SGLT-2i group showed a statistically significant increase in erythrocyte count (3.88 to 4.19 × 10^6/uL, P < 0.001), hemoglobin (11.20 to 11.70 g/dL, P < 0.001), and hematocrit values (34.4 to 36.5%, P < 0.001). However, the same changes were not observed in the DPP-4i group: erythrocyte count (3.87 to 3.91 × 10^6/uL, P = 0.051), hemoglobin (11.30 to 11.40 g/dL, P = 0.315), and hematocrit values (34.4 to 34.7%, P = 0.102). The Δhemoglobin showed a significant correlation with the SGLT-2i use, metformin use, erythrocyte count, hematocrit, hemoglobin and eGFR levels at baseline. Multiple regression analyses showed that use of SGLT-2i might be the main influencing factor.

Conclusion: Our study compared the effects of SGLT-2i and DPP-4i on erythropoietic parameters in T2D patients, and only the SGLT-2i group showed significant increase in erythrocyte count, hemoglobin, and hematocrit. The use of SGLT-2i may be the major factor affecting the improvement of erythropoietic parameters. Therefore the hypoglycemic effect of SGLT-2i may be accompanied by the improvement of anemia.

ROLE OF NEUTROPHIL EXTRACELLULAR TRAPS IN DIABETIC KIDNEY DISEASE: DATA FROM INTEGRATION OF BULK RNA AND SINGLE-NUCLEUS RNA SEQUENCING ANALYSES
Ruiyan Xie1,2, Litong Zhu1,2, Sher Ka Ho Jason1,2 and Desmond Yap1,2
1The University of Hong Kong, Hong Kong, P.R. China and 2Queen Mary Hospital, Hong Kong, P.R. China

Background and Aims: Neutrophil extracellular traps (NETs) is an important immune response against infections that is implicated in various immune-mediated conditions. Growing evidence shows that inflammation has key pathogenic contributions in diabetic kidney disease (DKD) but the role of NETs remains unclear.

Method: We evaluated the differentially expressed genes (DEGs) of NETs in human DKD using the bulk RNA sequencing datasets of kidney biopsy from DKD patients (GSE30528 and GSE30529). The candidate genes were further selected based on the machine learning algorithms (LASSO and SVM-RFE). The single-nucleus RNA sequencing (GSE195460 and GSE131882) and DKD bulk RNA sequencing (GSE30122) were used to validate the results. Receiver Operating Characteristics (ROC) curve were constructed to assess the diagnostic performance of the identified genes for DKD. Candidate drugs were further screened from the DSigDB database.

Results: Three characteristic genes (ITGAM, ITGB2 and TLR7) were selected using machine learning approach, which all were upregulated in human DKD glomerular and tubulointerstitial portion compared to healthy controls (all P < 0.05). Single-cell analysis further demonstrated that ITGAM, ITGB2 and TLR7 were mainly overexpressed in leucocytes. ITGAM, ITGB2 and TLR7 expression in tubulointerstitial compartment also showed good diagnostic performance for DKD (ROC AUC 0.983, 0.975 and 0.958 respectively). Candidate drugs that target ITGAM, ITGB2 or TLR7 genes in DKD include ropivacaine, lidocaine and sulfasalazine.

Conclusion: ITGAM, ITGB2 and TLR7 may serve as biomarkers for DKD and drugs that target these genes may have therapeutic potential for DKD.

Figure 1: Intersected neutrophil extracellular traps (NETs) associated genes in human diabetic kidney disease (DKD) datasets. *p<0.05, **p<0.01, ***p<0.001.
Figure 2: Three identified NETs related genes (ITGAM, ITGB2 and TLR7) expression validated in in human DKD bulk and single-nucleus RNA datasets.

UTILITY OF BLOOD KETONE MONITORING IN HAEMODIALYSIS PATIENTS UNDER INPATIENT NEPHROLOGY CARE

Ailsa Doak, Sophie Coleman, James Hills, Rona Hutton, Colin C. Geddes and Kate Stevens

Glasgow Renal and Transplant Unit, Glasgow, United Kingdom

Background and Aims: There is a lack of evidence regarding the relationship between capillary blood glucose (CBG) >15 mmol/L and blood ketones in maintenance haemodialysis dialysis patients meaning the utility of ketone measurement in this group is uncertain. Despite this, guidance published by the Joint British Diabetes Society for Inpatient Care (JBDS-IP) in 2022 states that blood ketones should be measured in patients on maintenance haemodialysis with diabetes mellitus (DM) who have pre- or post-dialysis CBG >15mmol/L and symptoms consistent with diabetic ketoacidosis (DKA), acknowledging that these can be non-specific [1]. We sought to identify if there is a relationship between elevated CBG and blood ketone levels in haemodialysis patients, and if haemodialysis affects blood ketone levels.

Method: Maintenance haemodialysis patients with DM admitted to a single ward over 2 separate 2 month periods were included. Nursing staff recorded CBG and blood ketone levels pre- and post-dialysis using a FreeStyle PrecisionPro ketone meter. For each patient, further demographic data were collected from the electronic patient record.

Results: 79 measures were collected from 30 patients, with between 1 and 7 measures for each patient. 57% patients (n = 17) were male, 37% (n = 11) had T1DM, and 80% (n = 24) were on insulin therapy. The median pre-HD CBG for all measures was 10.5mmol/L (IQR 8.15-15.05), median post-HD CBG was 9.1mmol/L (IQR 6.8-12.95), median pre-HD ketones were 0.1mmol/L (IQR 0.1-0.2) and median post-HD ketones were 0.1mmol/L (IQR 0.1-0.3). There was no significant difference in blood ketones pre-and post-HD for all measures (p = 0.09) (Figure 1). For measures where pre-HD CBG was >15mmol/L (n = 21) median pre-HD and post-HD ketones were 0.1 (IQR 0.1-0.2) and 0.2mmol/L (IQR 0.1-0.2) respectively (p = 0.45). For measures where pre-HD CBG was >20mmol/L (n = 6) median pre-HD and post-HD ketones were 0.1 mmol/L (IQR 0.1-0.13) and 0.2 mmol/L (IQR 0.1-0.2) respectively (p = 0.13). For measures where pre-HD CBG was <15mmol/L, median pre-HD ketones were 0.1 (IQR 0.1-0.2). There was no significant difference in blood ketones pre-HD between those with a pre-HD CBG >15mmol/L and those with a pre-HD CBG <15mmol/L (p = 0.69).

Conclusion: These results demonstrate no significant relationship between elevated CBG measures (>15mmol/L) and blood ketone levels in haemodialysis patients, nor do they demonstrate a significant change in blood ketone levels post haemodialysis. Unwell haemodialysis patients with elevated CBG clearly warrant medical assessment, but there is a lack of evidence that blood ketones are useful to aid assessment and guide management of these patients.

RENAAL ARTERY STENOSIS: A SINGLE CENTRE STUDY
Laura Panaro¹, Matteo Trezzi¹, Sonila Mocka¹, Michele Marchini¹, Francesca Viazzi² and Lucio Manenti¹

¹Ospedale Civile Sant’Andrea, Nefrologia e Dialisi, La Spezia, Italy and ²IRCCS Ospedale Policlinico San Martino, Nefrologia, Dialisi e Trapianto, Genova, Italy

Background and Aims: Renal artery stenosis (RAS) is present from 1% to 5% in people affected by arterial hypertension and it is often associated with peripheral artery disease and coronary artery disease; as the matter of fact, it is commonly found in people undergoing cardiac catheterization (18-20%) or angiography for aorto-iliac and lower extremities diseases. The major cause of renal artery stenosis is an atherosclerotic lesion localized in the proximal segment or to the ostium. Clinical presentations are renovascular hypertension and ischemic nephropathy. The aim of the study is to define either endovascular treatment gives a significant benefit on renal function and blood pressure control, when associated to medical therapy.

Method: This is a retrospective study focused on patients who underwent renal artery angioplasty and stenting in the last ten years, from November 2011 to April 2021 in the Nephrology Department, at Sant’Andrea Hospital, La Spezia (Italy). The primary outcome was kidney function, while secondary outcomes were blood pressure and the number of antihypertensive drugs one year after the revascularization. Patients included in the study had uncontrolled and refractory arterial hypertension (PA ≥ 140/90 mmHg) and/or progressive worsening of renal function, secondary to bilateral or unilateral stenosis in one functional kidney, that was identified at the color-doppler ultrasound examination by a peak systolic velocity (PSV) > 200 ml/min and an aortic-renal ratio > 3.5. We found 36 patients who had these characteristics. They were all affected by chronic kidney disease (CKD) (mean ± SD eGFR 25.3 ± 15.3 ml/min/1.73 m²) equally divided into stage 3 (33%, eGFR 30-60 ml/min/1.73 m²), stage IV (31% eGFR 15-29 ml/min/1.73 m²) and stage V (36%, eGFR <15 ml/min/1.73 m²).

Results: Kidney function, measured as serum creatinine (Scr) (mg/dl), improved immediately after the revascularization (mean ± SD Scr after vs before 2.52 ± 1.61 vs 3.31 ± 2.47 mg/dl p < 0.05), after 30 days (mean ± SD Scr after vs before creat. 2.36 ± 1.53 vs 3.19 ± 2.39 mg/dl p < 0.05) and after one year (mean ± SD Scr after vs before creat. 2.04 ± 1.16 vs 2.99 ± 2.40 mg/dl p < 0.05) (Fig. 1). Regarding arterial hypertension, a significant reduction of both systolic (SBP) and diastolic (DBP) blood pressure was detected in...
the subgroup of people under 75 years old (mean ± SD SBP after vs before, 144,62 ± 12,55 vs 168,18 ± 36,40 mmHg, p<0.01; after one year vs before, 143,93 ± 21,10 vs 167,83 ± 38,16 mmHg, p<0.05) (mean ± SD DBP after vs before, 73,62 ± 9,62 vs 83,07 ± 21,75 mmHg, p<0.05; after one year vs before 75,20 ± 9.02 vs 83,33 ± 23,10 mmHg, p = 0.07) (Fig. 2). The number of antihypertensive drugs dropped immediately after the angioplasty (mean ± SD tablets after vs before, 2,28 ± 1,11 vs 3,21 ± 1,43, p<0.01), while after one year there was not a significant increase of therapy (mean ± SD tablets after one year vs before, 3,00 ± 1,41 vs 3,23 ± 1,42, p = 0.47), even if blood pressure was better controlled than before the procedure with the same amount of tablets (Fig. 3).

Conclusion: Although our population was quite small, we demonstrated the advantages of renal artery revascularization in atherosclerotic renovascular disease, as demonstrated by kidney function and blood pressure control. Our results contrast the larger studies considered, that found no relevant clinical benefit on renal function and incidence of major adverse cardiovascular and renal events by comparing patients treated with medical therapy alone or with medical therapy plus angioplasty. The different conclusions are probably due to our strict adherence to the endovascular treatment indications, which consider the revascularization as the optimal strategy for a well-defined population.

CALCULATION OF THE RISK OF CONTRAST-INDUCED ACUTE KIDNEY DAMAGE IN THE CUTANEOUS CORONARY INTERVENTION IN PATIENTS WITH DIABETES MELLITUS

Baxodir Nigmonov, Shavkat Muminov and Durdona Saipova

Tashkent Pediatric Medical Institute, Internal Disease, Nephrology and Haemodialysis, Tashkent, Uzbekistan

Background and Aims: Analysis of the pathogenetic mechanisms of the development of contrast nephropathy in patients with coronary artery disease on the background of type 2 diabetes mellitus and the effectiveness of the proposed preventive measures.

Method: The study took place in two stages. The study included 56 patients with type 2 diabetes, the average age of the patients was 58 years, the CG consisted of 20 healthy persons. In most patients, the reason for which the endovascular radiopaque procedure (EVRCP) was performed was associated with atherosclerotic lesions: coronary artery disease, chronic lower limb ischemia (CLLI), atherosclerosis of the brachiocephalic arteries (BCA). EVRCP was performed on the vessels of the coronary basin, BCA, abdominal aorta and its branches, lower extremities. A retrospective analysis included a comparative analysis of two groups of diabetic patients who underwent EVRCP: 29 patients who developed CI-AKI (CI-AKI+ group) and 27 patients in whom the post-procedure period was uneventful. CI-AKI was defined as an increase in venous creatinine concentration of more than 25% by the end of 48 hours after EVRCP. During this phase of the study, the patient's medical history was analyzed - their anamnestic data, glycemic status, general urinalysis, kidneys, estimated glomerular filtration rate (eGFR) initially, 2,4,6,8 and 10 days after the procedure. The first stage, a retrospective one, included a comparative analysis of two groups of diabetic patients who underwent an endovascular radiopaque procedure (EVRCP): 29 patients who developed CI-AKI (CI-AKI+ group) and 27 patients in whom the post-procedure period was uneventful. CI-AKI was defined as an increase in venous creatinine concentration of more than 25% by the end of 48 hours after EVRD.
Results: Based on the analysis, we developed a risk scale for the development of CI-AKI in patients with DM. In the process of compiling the scale, the value of RR for the development of CI-AKI in the presence of the corresponding factor, rounded to the nearest whole number, was used as risk coefficients. According to the developed scale, in the presence of a risk factor, the patient is assigned a certain score. The score determines the risk of CI-AKI.

Conclusion: Thus, the present study showed that in patients with DM, compared with healthy volunteers, there is a change in kidney function, which is more pronounced in individuals prone to the development of CI-AKI. Changes in the cellular and biochemical blood composition in patients with DM are characteristic of diabetic nephropathy and are also more pronounced in patients at risk of CI-AKI.

MRI PREDICTORS OF DIASTOLIC DYSFUNCTION OF THE LEFT VENTRICLE
Dano Egamberdiev1, Iroda Ruzmetova1, M. Khodjibekova Yu2 and A Karimova Yu2
1Tashkent Pediatric Medical Institute, Internal Medicine, Nephrology and Hemodialysis, Tashkent, Uzbekistan and 2Tashkent State Dental Institute, Internal Medicine, Tashkent, Uzbekistan

Background and Aims: Non-invasive assessment of diastolic dysfunction remains challenging, this study aims to identify the most informative cardiac magnetic resonance imaging (CMR) parameters for assessing left ventricular diastolic dysfunction (LVDD).

Objective: To study MRI parameters as predictors of left ventricular diastolic dysfunction (LVDD) in patients with suspected heart failure.

Method: The study included 239 patients cases with heart failure were identified during the study. The CMR measurements of the patients’ heart chambers were obtained from an independent manual examination using an image archiving and transmission system. CMR measurements were performed as follows. The patients were examined with a 1.5 Tesla MRI machine and eight-channel cardiac coils were used to acquire the image. The position and orientation of the heart in the chest were determined after cardiac reference images of the chest were taken. Using stationary free precession sequences, a two-chamber image of the left ventricle was obtained with a breath hold of 10 – 15 seconds at the end of exhalation (image parameters: repetition time 3.6 ms; echo time 1.6 ms; 350 mm; slice thickness 6 mm; gap 2 mm; angle of rotation 45°, 14 projections per segment, matrix 224 160). Four-chamber short axes and three-chamber sequences were then obtained. The right ventricular end-diastolic size (EDD) diameter was measured between the right ventricular endocardium and the interventricular septum, parallel to the tricuspid valve and 1 cm distal to the valve on four-chamber sinusoids with free precession (SSFP).

Results: As a result the left atrial enlargement is the most prognostic factor for diastolic dysfunction (DD) among the assessed complex MRI parameters. TBI and tissue tracking reflect internal aberration, revealing abnormal deformity patterns in the basolateral segments compared to patients with normal diastolic function. Based on the quantitative assessment of the size of the LA, it is possible to determine the threshold value for the detection of DD. In addition, it was found that the quantitative assessment of LV diastolic deformity is predictive for identifying patients with DD. Increased LA dimensions have a diagnostic accuracy according to our data for detecting diastolic dysfunction (DD).

Conclusion: Tissue tracking and TRM reveal impaired diastolic deformity of the basal-lateral wall in DD as a direct sign of DD.

EFFECT OF SGLT2I ON URIC ACID AND GLUCOSE URINARY FRACTIONAL EXCRETION IN PATIENTS WITH CHRONIC KIDNEY DISEASE AND TYPE 2 DIABETES MELLITUS
Paula Sanchez Briales, Maria Marques Vidas, Paula López, María Victoria López Illazuey, Aylin Vedat Ali and Jose Portoles
Hospital Universitario Puerta de Hierro Majadahonda, Nephrology, Majadahonda, Spain

Background and Aims: Sodium-glucose cotransporter type 2 inhibitors (SGLT2i) have demonstrated broad benefits beyond glycemic control, including hypouricemic effects. However, this fact has not been completely validated in chronic kidney disease (CKD). The mechanism by which SGLT2i produces an increase in uric acid elimination is not fully understood and appears to be mediated in part by increased glucose in the renal tubule, which would compete in reabsorption with uric acid through GLUTb transporter. The aim of this study is to analyse the effect of SGLT2i on uric acid and glucose urinary fractional excretion (FE) in type 2 diabetes mellitus (T2DM) + CKD patients.

Method: Retrospective observational single-center study conducted between January 18 and December 22 in T2DM-CKD patients on SGLT2i. Subjects on renal replacement therapy, treatment with GLP1 analogues and those for whom we did not have uricosuria prior to the start of ISGLT2 were excluded. Urinary uric acid and glucose FE were analysed at baseline and during follow-up of up to 24 months, with 3, 6 and 12 months cut-offs. Data are described as mean and standard deviation (SD). Statistical analysis was performed using STATA v14 with statistics for paired samples.

Results: 82 patients were included in the study, with a mean follow-up of 1.2 years. During follow-up, 23 patients left the study (arGLP1 initiation (n = 9), adverse reactions (n = 4), exitus (n = 2) and loss to follow-up (n = 8). 78.1% were male, mean age 72.7 years (SD 8.5), and main co-morbidities were: obesity 76.8%, arterial hypertension 95%, hyperuricemia 75.6% and congestive heart failure 25.6%. Distribution according SGLT2i drug was: 65.6% dapagliflozin, 25% canagliflozin and 9.4% empagliflozin. eGFR decreased immediately after initiation of SGLT2i with ulterior stabilization as described elsewhere (Table 1). We observed a significant increase on urinary uric acid FE that remained stable along the follow-up: basal 7.4%, 3 months 9.4% (p < 0.001). However, serum uric acid levels did not show significant differences along the study. Urinary glucose FE increase remained stable along the whole observation period in spite of no significant differences from a clinical point of view on % of glycosylated haemoglobin (Table 1).

Conclusion: Despite decreased GFR, T2DM-CKD patients exhibited significant urinary uric acid and glucose FE increase after starting SGLT2i. This increase remained stable for at least 2 years. However, we did not observe significant reductions on uricemia in these patients, implying that increase on urinary uric acid excretion is not enough in this setting to obtain significant modifications on uricemia.
### Abstracts

**Background and Aims:** The use of GLP-1 receptor agonist (ra) has become one of the cornerstones for CKD type 2 diabetic patients (T2DM) treatment. Oral formulation of semaglutide appeared as new therapeutic tool to increase the use of drugs with proved renal benefit. However, method of administration of the oral formulation and oral absorption limitations in CKD patients could adversely affect drug efficacy. The aim of this study was to compare the efficacy of semaglutide sbc vs oral in CKD patients.

**Method:** Prospective, real-world study performed in T2DM-CKD patients with indication of initiation of GLP-1ra therapy in which semaglutide sbc or oral was initiated. Patients were assigned to sbc or oral formulation according to drug accessibility and patient preferences. Patients previously treated with any other GLP-1ra were excluded.

**Results:** 70 patients were included, 50 with sbc and 20 with oral semaglutide with mean follow up time of 407 [180-753] and 154 [75.5-205] days respectively.

**Conclusion:** Oral formulation of semaglutide was equally effective in terms of glucose control and body weight in patients with T2DM and CKD even with more patients on the low-medium doses. Gi side effects were similar with both formulations though the lower number of patients on the higher oral dose does not allow further conclusions.

Conclusion: The data suggest that in diabetic nephropathy, the eNOS T786C allele may be involved in endothelial dysfunction. Azerbaijani patients showed dominance of the C allele and a mutant homozygous genotype CC of the T786C gene of eNOS.

#2965
DYNAMICS OF THE FUNCTIONAL STATE OF THE KIDNEYS IN PATIENTS WITH DIABETES MELLITUS AND A HIGH RISK OF CI-AKI AND THE USE OF PREVENTIVE MEASURES
Baxodir Nigmonov, Shavkat Muminov and Durdona Saipova
Tashkent Pediatric Medical Institute, Internal Disease, Nephrology and Haemodialysis, Tashkent, Uzbekistan

Background and Aims: Analysis of the pathogenetic mechanisms of the development of contrast nephropathy in patients with coronary artery disease on the background of type 2 diabetes mellitus and the effectiveness of the proposed preventive measures.

Method: The study included 56 patients with type 2 diabetes, the average age of the patients was 58 years, the CG consisted of 20 healthy persons. In most patients, the reason for which the endovascular radiopaque procedure (EVRCP) was performed was associated with atherosclerotic lesions: coronary artery disease, chronic lower limb ischemia (CLLI), atherosclerosis of the brachiocephalic arteries (BCA). EVRCP was performed on the vessels of the coronary basin, BCA, abdominal aorta and its branches, lower extremities. A retrospective analysis included a comparative analysis of two groups of patients with type 2 diabetes who underwent (EVRCP): 29 patients who developed CI-AKI (CI-AKI+ group) and 27 patients in whom the post-procedure period was uneventful. CI-AKI was defined as an increase in venous creatinine concentration of more than 25% by the end of 48 hours after EVRCP. During this phase of the study, the patient's medical history was analyzed - their anamnestic data, glycemic status, general urinalysis, kidneys, estimated glomerular filtration rate (eGFR) initially, 2,4,6,8 and 10 days after the procedure.

Results: The CI-AKI+ and CI-AKI- groups were compared in terms of clinical and anamnestic, hematological, urological data and the results of echocardiography and renal ultrasound with each other and with representatives of the CG. The CI-AKI+ and CI-AKI- groups did not differ in nosological distribution (Fig. 1): in both groups, half of the patients with EVRCP were performed due to the presence of coronary pathology (51.72% and 48.15%, respectively), the rest in patients it was comparable for CCI and CVD (27.59% and 26.09% in the CI-AKI+ group and 25.93% each in the CI-AKI- group).

Conclusion: Taking into account the OR of CI-AKI in patients with DM in the presence of identified predictors, a risk scale was developed. A risk score of 28 points or more demonstrates a predictive sensitivity in terms of the development of CI-AKI of 96.55% (p<0.001).

#3423
DIAGNOSTIC SIGNIFICANCE MAGNETIC RESONANCE IMAGING IN CHRONIC HEART FAILURE OF VARIOUS GENESIS
Dano Egamberdieva 1,2, Iroda Ruzmetova 2, M. Khodjibekova Yu 2 and A Karimova Yu 3

1 Internal Medicine, Nephrology and Hemodialysis, Tashkent, Uzbekistan, 2 Tashkent Pediatric Medical Institute, Internal Medicine, Nephrology and Hemodialysis, Tashkent, Uzbekistan and 3 Tashkent State Dental Institute, Internal Medicine, Tashkent, Uzbekistan

Background and Aims: Based on a comparative assessment of radiological, ultrasound, clinical and laboratory studies, to determine the diagnostic significance of magnetic resonance imaging (MRI) in the heart disease.

Method: We analyzed echocardiographic and magnetic resonance imaging of the heart in 40 patients who were examined and treated in the cardiology departments of the Republican Medical Specialized Scientific and Practical Center for Therapy and Medical Rehabilitation. The information content of the use of instrumental research methods in patients with chronic heart failure was evaluated. Information on demographic characteristics, including age, gender, education, occupation, was collected from doctors visits using a standard questionnaire.

Results: The average age of patients was 57 years. 40% of the surveyed were made up of men. When studying risk factors for the disease, 49% of all patients had arterial hypertension, 18% had type 2 diabetes mellitus, 21% of patients were active smokers, and 11% had a family history of risk of cardiovascular disease. 36% of patients had a history of myocardial infarction, percutaneous coronary interventions. The mean LV EF was 42% and the mean right ventricular EF (RV EF) was 48%. In patients with CHF of ischemic origin, in the vast majority of cases, the results of echocardiographic and MRI examinations of the heart were comparable. The conducted MRI of the heart had an additional informative value in case of doubtful ECG and EchoCG data, as well as in differential diagnosis. The results of MRI were more accurate in determining the etiology of myocardial hypertrophy, in particular hypertrophic cardiomyopathy.

Conclusion: The diagnostic value of cardio-MRI showed great diagnostic value in the diagnosis of ischemic damage and non-coronary diseases of the myocardium.

GENERATIVE ARTIFICIAL INTELLIGENCE FOR CREATION OF SYNTHETIC HYPERTENSION TRIAL DATA
Chirag Jain and Conor Judge
University of Galway, Galway, Ireland

Background and Aims: Synthetic data can be an effective supplement or alternative to real data for the training of machine learning models. Synthetic data may also be used to evaluate new tools, develop educational curricula, or remove undesirable biases in datasets. We aim to evaluate four synthetic data generation methods applied to hypertension randomized clinical trial data.

Method: The Systolic Blood Pressure Intervention Trial (SPRINT) trial data showed that intensive BP control to SBP <120 mm Hg results in significant cardiovascular benefits in high-risk patients with hypertension compared with routine BP control to <140 mm Hg. The Synthetic Data Vault (SDV) is a Synthetic Data Generation ecosystem of libraries that allows users to easily generate new Synthetic Data that has the same format and statistical properties as the original dataset. SDV supports multiple types of data, including date-times, discrete-ordinal, categorical, and numerical. SPRINT data was pre-processed to create a single table of 140,000 patient visits with baseline variables (age, sex, race, aspirin use, estimated Glomerular Filtration Rate (eGFR)) and visit level variables (systolic and diastolic blood pressure, heart rate and total number of antihypertensive medications at end of visit). Using the SDV library for python, we used four generative models to create synthetic SPRINT data, 1) Gaussian copula model, 2) Conditional Tabular Generative adversarial network (CTGAN), 3) CopulaGAN model, and 4) Tabular Variational Auto-encoder (TVAE). We evaluated the results using the SMetrics library which includes the shapes of the columns (marginal distributions), the pairwise trends between the columns (correlations), reproduce mathematical properties from your original data and new row synthesis. Finally, an overall quality score which represents an amalgamation of the marginal distribution and correlations was computed, where 0 indicates the lowest quality and 1 indicates the highest.

Results: Two hundred thousand synthetic patient visits were created for each method. The overall quality scores in order were 90.67% for Gaussian copula, 86.77% for TVAE, 81.03% for CTGAN, and 79.7% for CopulaGAN. The column shape score which represents the marginal distribution was highest for Gaussian Copula (94.54%), followed by TVAE (88.44%), CTGAN (82.35%), and Copula GAN (80.27%). The column pair trend which corresponds to correlations was highest for Gaussian Copula (86.8%), followed by TAVE (85.1%), CTGAN (79.72%), and Copula GAN (79.12%).

Conclusion: Gaussian copula created the highest scoring synthetic SPRINT data based on the marginal distribution, correlations, and overall score. The Synthetic Data Vault is a feasible collection of methods for generation of synthetic clinical trial data for training future machine learning and AI models.

Background and Aims: Women with CKD stages 3-5 are at higher risk of adverse pregnancy outcomes, including preterm delivery and low birthweight and progression of kidney disease. However, data describing outcomes of women with less severe kidney disease are limited, and few compare with women normal renal function. Furthermore, most studies report cohorts recruited from specialist clinics and may not be representative. This study aimed to describe pregnancy outcomes in a UK population cohort according to pre-conception eGFR <90 ml/min/1.73 m² compared with women with eGFR ≥90 ml/min/1.73 m².

Method: Routinely collected pregnancy data from three NHS Trust hospitals in Kent (UK) between 2010 and 2020 were extracted with Research Ethics Committee approval (19/LO/1242 and 18/SC/0158). Local laboratory and clinical data were linked to identify women with eGFR measured within two years of conception. Women without preconception creatinine were excluded from analysis. Baseline characteristics were described and comparisons between eGFR and adverse pregnancy and renal outcomes were tested.

Results: A total of 14,243 pregnancies with confirmed pre-pregnancy creatinine were included, of which 1,405/14,243 (9.9%) had CKD stages 1-4 (stage 1: 221/14,243 (1.6%), stage 2: 1,170/14,243 (8.2%), stage 3: 12/14,243 (0.1%), stage 4: 2/14,243 (0.01%) (Table 1). Women with pre-pregnancy eGFR 60-89 ml/min/1.73 m² (stage 2) were significantly older at conception than women without CKD (eGFR >90 ml/min/1.73 m²) but there were no significant differences in live birth rates, small for gestational age, gestation at delivery, and preterm birth. In pregnancies with CKD (1,405, stages 1-4), pre-pregnancy eGFR was weakly correlated with birthweight (r = 0.05, p = 0.05), and gestational age (r = 0.06, p = 0.05).

Conclusion: To our knowledge, this is the largest population cohort to describe pregnancy outcomes between women with eGFR 60-89 ml/min/1.73 m² compared with eGFR ≥90 ml/min/1.73 m². Women with eGFR 60-89 ml/min/1.73 m² did not have worse renal or pregnancy outcomes compared to eGFR >90 ml/min/1.73 m². Limitations include lack of proteinuria data and details of structural CKD (Class 1 CKD), and only one eGFR measurement prior to pregnancy may have led to some women with temporary reduction in function being included in the cohort. Overall, the findings suggest that women with eGFR 60-89 ml/min/1.73 m² should not be discouraged from pregnancy.

HYPERTENSION, HYPOKALEMIA AND PREGNANCY: A CASE OF GELLER SYNDROME

Amara Sarwald and Jo Abraham

University of Utah, Division of Nephrology, United States of America

Background and Aims: Hypokalemia is not a common laboratory finding in pregnancy, with a recent study revealing a prevalence of less than 1%, nationwide [1]. In a pregnant patient with newfound hypertension and hypokalemia, it is important to consider causes that would affect the Renin-Angiotension-Aldosterone pathway. Although these causes are usually suspected in patients with a triad of hypertension, hypokalemia and metabolic alkalosis, the latter finding may not be present in pregnant patients given metabolic compensation for their respiratory alkalosis of pregnancy.

Method: A 27 year old, 36 week and 5 day pregnant female presented to her OBGYN follow up appointment at the beginning of the year. At that time, she was found to be hypokalemic and was admitted overnight for potassium repletion, consisting of 40 mEq of oral potassium chloride and 40 mEq of intravenous potassium. She was discharged after that with a follow up appointment scheduled the next month. At that clinic visit, her potassium was 2.6 mmol/L and she was admitted for further workup. The patient was also hypertensive, with a blood pressure markedly increased from her baseline value. The patient endorsed having elevated blood pressures during her previous pregnancy with normalization after delivery. She stated that she was followed at a different outpatient clinic at that time, so she did not have all the records, however was told she suffered from pre-eclampsia. During this current admission, patient did note dyspnea, fatigue and generalized weakness. She denied any diarrhea or gastrointestinal distress. Her physical examination was unremarkable. Spot urine potassium was 19 with a serum potassium of 2.8 mmol/L after 40 mEq of potassium supplementation. Aldosterone was <3 ng/dL and renin was 4.8 pg/mL. Urine protein to creatinine ratio was 167 mg/g with normal liver enzymes. Her magnesium level was 1.8 mg/dL. The patient had a vaginal delivery with improvement in blood pressure. No antihypertensive agents were required. During subsequent outpatient visits, her potassium also started to improve and she was eventually weaned off supplementation. Given an unremarkable physical examination along with hypokalemia and hypertension which resolved after delivery, a diagnosis of Geller syndrome was made. Genetic testing was considered but could not be performed.

Results: In Geller syndrome, a gain-of-function mutation allows progesterone to bind and stimulate the mineralocorticoid receptor. Clinically, this presents as a patient who develops hypertension and hypokalemia during states of high circulating progesterone, such as pregnancy. Often these derangements resolve after cessation of high levels of progesterone, such as delivery of fetus, without major intervention.

Conclusion: High clinical suspicion is needed for pregnant patients who present with hypertension and hypokalemia. Reviewing records of past pregnancies can often shed light in this patient population, specifically the resolution of the blood pressure and potassium derangements after delivery of fetus. Newer evaluation techniques, such as genetic testing, can also play an important role with identifying this condition and allowing for counselling prior to subsequent pregnancies. Treatment typically consists of electrolyte supplementation and blood pressure control until birth occurs.

MACHINE LEARNING-BASED HYPERTENSION DISEASE RISK CLASSIFICATION USING LEARNING VECTOR QUANTIZATION ALGORITHM

Rifaldy Fajar, Sahnaz Putri and Elfiaya Syafruddin

Yogyakarta State University, Computational Biology and Medicine Laboratory, Sleman, Indonesia

Background and Aims: According to the World Health Organization, the disease dubbed as the silent killer of death is the number one cause of death in the world. Hypertension is a disease that does not show certain symptoms. There are about 95% of hypertension cases have no known cause, while the rest are caused by other diseases. Therefore, an early detection system for hypertension is needed. In this research, the Learning Vector Quantization (LVQ) algorithm is used to perform the classification process.

Method: In this research, the LVQ machine learning algorithm is used. LVQ is an algorithm that is a type of artificial neural network and uses neural computation. The data in this study is hypertension patient data from Sultan Daeng Radja Hospital which is divided into four classes. In the system design stage using the LVQ algorithm, the process in this system is by entering input data in the form of medical records consisting of 12 attributes based on their weights which will then be carried out by the LVQ process to produce classification results. If the classification results have been obtained, the system will stop. After the classification testing process is carried out, the accuracy calculation process is carried out.

Results: Based on six test scenarios that have been carried out, the system produces recommendations for a value of 0.1 for the learning rate, a value of 0.2 for the learning rate multiplier, the amount of training data of as much as 50%, the maximum epoch value of six, the minimum value of alpha 0.001. From these values, the average accuracy result obtained is 94%.

Conclusion: Based on the value of accuracy results obtained exceeding 90%, these values, the average accuracy result obtained is 94%.

DIFFERENTIATING POSTPARTUM HELLP SYNDROME FROM ATYPICAL HEMOLYTIC UREMIC SYNDROME

Michael Che1, Sarah Moran2, Richard Smith3, Sara Gastoldi4 and Jocelyn Garland5

1 University of Ottawa, Department of Medicine, Ottawa, Canada, 2 University College Cork, Department of Nephrology, Cork, Ireland, 3 Roy J. and Lucille A. Carver College of Medicine, Molecular Otolaryngology and Renal Research Laboratories, Iowa City, United States of America, 4 Istituto Di Ricerche Farmacologiche Mario Negri, Italy and 5 Queen’s University, Department of Medicine, Kingston, Canada

Background and Aims: HELLP (hemolysis, elevated liver enzymes, low platelets) is a severe variant of preeclampsia whose pathogenesis remains unknown but likely involves abnormal placentalation, endothelial dysfunction and release of vasoactive substances. Complement dysregulation is implicated in the pathogenesis of atypical hemolytic uremic syndrome (aHUS) and there is growing evidence to support its role in HELLP syndrome. Here we present a case of postpartum thrombotic microangiopathy (TMA) in the setting of HELLP syndrome.

Method: We present a case report. Ethics approval was obtained by the Queen’s University Health Sciences and Affiliated Teaching Hospitals Research Ethics Board.

Results: A 22 year old G1P1 Caucasian woman presents at 37 weeks gestation with abdominal pain and severe hypertension. Labs demonstrated TMA including hemoglobin 95, platelets 30, LDH 2397, and schistocytes. She had severe transaminitis with AST 1845 and ALT 830, and proteinuric acute kidney injury. She was diagnosed with HELLP syndrome and treated with anti-hypertensives and emergency Caesarean section. Unfortunately, the infant did not survive, and there was no placental abruption. Platelets recovered by day 5 postpartum, LDH by day 7. However, renal function worsened and by day 6 postpartum, she required hemodialysis. A renal biopsy revealed acute and chronic TMA. She did not have cortical necrosis. Further workup revealed normal C3, C4 and ADAMTS13 levels. Dialysis was stopped after two weeks. By 6 months, her renal function and proteinuria returned to normal. Complement function testing revealed negative complement factor H autoantibody, but elevated soluble CsA-9 (sCsA-9) level (0.42 mg/L, normal <0.3). Ex-vivo serum CsA-9 deposition on human microvascular endothelial cells was assessed both on resting (182%, normal <150%) and on ADP-activated endothelial cells (273%, normal <150%). This test was repeated 6 months postpartum when renal function had normalized, and results were persistently abnormal both on resting (215%, normal <150%) and on ADP-activated endothelial cells (282%, normal <150%). aHUS genetic testing was negative.

Conclusion: Results from Burwick et al suggest that this patient had a very high likelihood of clinical aHUS in association with HELLP syndrome (elevated LDH >1832 U/L and creatinine >1.9 mg/dL) [1]. Identifiable aHUS genetic mutations only occur in 50% of aHUS patients. Complement function testing is not routinely assessed for postpartum HELLP; however, the severity of her HELLP syndrome prompted further investigation (C5b-9 deposition testing). The persistence of increased C5b-9 deposition 6 months postpartum for this patient mimics the findings of patients who have confirmed aHUS [2]. Our patient’s unique results suggest the patient may be at risk for recurrent TMA/aHUS in her lifetime, particularly if another pregnancy is being considered. Future research should explore which pregnancy associated TMA patients may benefit from anti-complement therapy.

Background and Aims: Atypical hemolytic uremic syndrome (aHUS) is a rare disease caused by dysregulation of the alternative pathway of complement, characterized by hemolytic microangiopathic anemia, thrombocytopenia and acute kidney injury. Incidence is ~ 0.23 per year per million people and about 7% of aHUS diagnoses occur in the setting of pregnancy, determining the so-called “pregnancy associated aHUS” (PaHUS). It could occur during gestation, in the immediate postpartum period or up to 12 weeks after delivery. Maternal exposure to semiallogenic fetoplacental material represents a complement triggering condition, worsened over gestation, with a climax at the delivery. Despite the attempt of solute and membrane regulators to mitigate the immune overactivation, an exaggerated inflammatory response, a decrease in the amount of regulatory proteins or some inherited or de novo mutations in complement factors’ genes, predispose to complement dysregulation. Its diagnosis is often delayed due to a multif orm manifestation and similarity with HELLP syndrome or other thrombotic microangiopathy disorders (TMA), such as thrombotic thrombocytopenic purpura. It results in a delayed treatment, consequently threatening mother and fetus life. PaHUS is linked to high rates of end stage kidney disease, nearly achieving 78% at 24 months’ postpartum without eculizumab therapy. Indeed, anti-C5 therapy is effective and universally considered the best choice to treat aHUS.

Method: In this case series, we report our experience about the management of PaHUS during the last 2 years. An internal hospital protocol points out suspected TMA patients semi-automatically, thanks to a structured teamwork among emergency department and laboratory, hematology, nephrology and intensive care units. Treatment protocol applied was standard eculizumab

Abstracts i1017
PREVALENE OF CHRONIC KIDNEY DISEASE IN PREGNANCY: A UK POPULATION STUDY

Elizabeth Ralston1, Yanzhong Wang1, Steve Childs4, Chris Farmer2, Ranjit Akolekar3 and Kate Bramham1

1King’s College London, School of Life Course and Population Sciences, Great Maze Pond, London, United Kingdom. 2University of Kent, Centre for Health Services Studies, United Kingdom and 3Medway NHS Foundation Trust, Medway Fetal and Obstetric Medicine Centre, United Kingdom

Background and Aims: Women with chronic kidney disease (CKD) are at greater risk of adverse pregnancy outcomes. Historically CKD in has been proposed to affect 3% of all pregnancies (0.13% with moderate to severe CKD) but is based on expert opinion and numbers affected are propose to rise due to the rise of maternal obesity and age and could impact on service planning. However, there are no accurate estimates of CKD prevalence in pregnancy. This study aimed to investigate how many pregnancies may be affected by CKD, according to disease severity, in a UK population cohort.

Method: Routinely collected pregnancy data from three NHS Trust hospitals in Kent (UK) between 2010 and 2020 were extracted with Research Ethics Committee approval (19/LO/1242 and 18/SC/0158). Local laboratory and health care records were linked and used to identify women between 18 and 50 years of age with a confirmed eGFR measurement (Chronic Kidney Disease Epidemiology Collaboration 2009 without ethnicity correction) within two years prior to conception, and no current pregnancy recorded at the time of sampling. Baseline characteristics and prevalence of CKD at different stages were described.

Results: A total of 76, 755 pregnancies were recorded between 2010 and 2020, including 14,257/76,755 (18.6%) pregnancies with preconception eGFR (median eGFR 115 ml/min/1.73 m²) (IQR 21). There were 1,184/14,257 (8.3%) pregnancies with a preconception eGFR <90ml/min/1.73 m², including eGFR between 60-89 ml/min/1.73 m² (1170/14,257, 8.2%). Only 12/14,257 (0.08%) of pregnancies had an eGFR 30-59 ml/min/1.73 m² and two pregnancies (0.01%) had an eGFR between eGFR 15-29 ml/min/1.73 m². There were no pregnancies in the cohort with an eGFR <15 ml/min/1.73 m². The cohort was majority White ethnicity (1291/135790; 94%) with 6.4% (879/135790) from Black, Asian, Mixed and East Asian ethnicities. Women with pregnancies that were affected with CKD were significantly older at conception (27, SD 5.5, vs 30.8, SD 5.5, p < 0.001) and had greater prevalence of chronic hypertension (8.6% vs 11.3%, p = 0.013). Considering the whole cohort, including those without kidney function testing, the proportion of pregnancies affected by CKD was low (1,185/76,755; 1.5%).

Conclusion: This is the largest cohort reporting the prevalence of CKD including severity in pregnancies in the UK. Overall the total number of pregnancies affected by CKD was lower than previous estimates, especially for those with advanced disease. This finding may represent reduced fertility in women with CKD, individual decisions not to conceive, negative advice from clinicians or obstetric management at different centres not captured in this cohort. However, only 1 in 5 women prior to pregnancy had an eGFR and gestational changes in creatinine may mask identification of CKD in pregnancy. A further limitation includes only eGFR measurement prior to pregnancy was used thus women with temporary eGFR reduction may have been incorrectly included in the CKD cohort. Finally there were few women from ethnic minority groups who are disproportionately affected by CKD. Further information regarding kidney function in women of reproductive age and at conception is needed to enable true estimated of CKD prevalence in obstetric care.

Equal contribution: Estela Nogueira and Rita Afonso

Background and Aims: Management of pregnant women with diabetic kidney disease and nephrotic range proteinuria or nephrotic syndrome constitute a challenge to clinicians. Maternal and perinatal outcomes, especially in patients with chronic kidney disease, remain poor. The authors describe the multidisciplinary approach and the outcomes of diabetic pregnant patients with nephrotic range proteinuria.

Method: Retrospective observational study in which the authors reviewed maternal, obstetric and perinatal outcomes in pregnant diabetic woman with nephrotic range proteinuria or nephrotic syndrome surveilled at our nephro-obstetric unit from 2011 until 2021.

Results: We evaluated 7 gestations in 6 patients. Mean age was 31.7±4.7 years (26-38), 5 were caucasian and 1 was black African, and 4 were nulliparas. They all had type 1 diabetes, with mean disease diagnosis at 9.9±5.9 years of age. All patients had chronic hypertension and 5/6 patients had poor glycaemic control before pregnancy (mean HbA1c of 11.9%). Mean baseline Scr was 1.1±0.5 mg/dl (0.5-2.8) and mean baseline proteinuria was 3697.2±2301.4 mg/day (73-6326), with 1/1/3/2 patients being on CKD stage 1/2/3/4, before pregnancy, respectively. Exposure to teratogenic therapy during the first trimester occurred in 5/7 gestations with a mean exposure of 7.4 ± 3.1 weeks. Proteinuria increased in all patients and renal function deteriorated in 5/7 gestations (mean Scr of 2.5±1.2; 0.67-4.07 mg/dl) in association with pre-eclampsia in 2 patients and with pregnancy hyperfiltration and nephrotic syndrome in all gestations. One patient started dialysis at week 28, due to urea levels >100mg/dL. Partial renal recovery occurred in 2 patients. To date, 3/6 patients initiated PD 15 months (6-29 months) after gestation, 1 of which received a kidney-pancreas transplant. Hypertension aggravated in 6 gestations. Aspirin and low molecular weight heparin were initiated in 6 gestations and they were all treated with furosemide to control volume overload. Regarding fetal outcomes, severe fetal growth restriction was responsible for 1 still birth and 1 medical termination of pregnancy, both at 24 weeks. Cesarean was performed in 4/5 gestations (one is still undergoing) due to pre-eclampsia, renal function deterioration and/or fetal growth restriction. Mean gestation age at delivery was 29.5±4.7 weeks, mean birth weight was 1389 ±203.3 mg (1190-1665) and mean apgar scores at 1/5/10 minutes were 9/10/10 respectively. Neonatal intensive care was needed in 4 newborns.

Conclusion: This study reinforces the idea that diabetic women with nephrotic range proteinuria have an increased risk of complications and worse outcomes during pregnancy, namely pre-eclampsia, fetal growth restriction, preterm delivery and renal function deterioration. As such, glycermic and proteinic control should be optimized and careful counseling regarding outcomes should be discussed before pregnancy. Management during gestation should involve an experienced multidisciplinary team including endocrinologist, nutritionist, nephrologist and obstetrician.
Figure 1: (A) Extracellular vesicles can effectively double dyeing by DID/DiI. (B) Define the optimal ratio of DID/DiI in extracellular vesicles. (C) The changes of MPO expression in AKI model were detected by WB and immunohistochemistry. (D) The changes of MPO expression in AKI model were detected by WB and immunohistochemistry.

**Conclusion:** In this study, we constructed in vivo imaging of extracellular vesicles in the kidney based on optical imaging. Chemiluminescence generated by inflammatory specific expression of MPO and detection of MPO enzyme activity and specific detection substance luminol in the kidney disease model formed fluorescence resonance energy transfer in extracellular vesicles of double-stained cells. Preliminary efficacy evaluation showed that the fluorescence intensity of the double-dyed extracellular vesicles system in this model is greater than that of the single-dyed extracellular vesicles. This method can be applied to the in vivo tracer of extracellular vesicles in the kidney, providing technical support for the treatment of extracellular vesicles in kidney disease and the study of drug delivery.

**IN VIVO TRACING OF EXTRACELLULAR VESICLES IN ACUTE KIDNEY INJURY**

Wei Jiang, Bin Wang and Bicheng Liu

Zhong Da Hospital, Southeast University School of Medicine, Nephrology, Nanjing, P.R. China

**Background and Aims:** Extracellular vesicles, with their unique ability to migrate, target, and selectively internalize into specific cells, open up a new field of diagnosis, treatment, and drug delivery. However, a major disadvantage of translating exosome therapy into the clinic is that not enough is known about these endogenous nanovesicles, especially in vivo, and the tracing of extracellular vesicles in vivo can yield important information about their biological distribution, migration capacity, toxicity, biological role and mechanism of action. Therefore, to develop efficient, sensitive and biocompatible exosome markers. Recording and imaging techniques are much needed. Recent studies have developed different exosome labeling and imaging methods. However, due to the physiological location of the kidney and the distribution characteristics of extracellular vesicles in vivo, the specificity of live imaging of extracellular vesicles in the kidney is insufficient. Therefore, this study intended to construct a reliable and specific in vivo imaging method of extracellular vesicles in the kidney.

**Method:** Dual-mode imaging was used to trace extracellular vesicles in mice model of kidney disease, providing important technical support for tracing extracellular vesicles in vivo kidney and related drug delivery. Firstly, extracellular vesicles were separated for fluorescence staining, and the concentration variation rule of MPO, a disease-specific enzyme, was mastered in mouse kidney tissue. MPO, Luminol, DiI and DiD were used to construct a near-infrared imaging mode based on fluorescence resonance energy transfer to enhance fluorescence penetration, and targeted peptides were used to increase the aggregation of extracellular vesicles in vivo. This combines the sensitivity of fluorescence imaging with the specificity of kidney targeting peptides to reach deep tissues of extracellular vesicles.

**Results:** In the optical mode in vitro experiments, we found that exosomes could be co-stained by DiL and DiD. In addition, the dye ratio of 3:7 could make exosomes exhibit the strongest excitation light. In the presence of luminol sodium, the fluorescence intensity of exosomes co-stained by DiI and DiD lipophilic dyes was higher than that of exosomes with single dye. In the second mode of MRI, we found that our material can be efficiently adsorbed on exosomes by electron microscopy. Follow-up in vivo experiments are being further improved.

**Conclusion:** In this study, we constructed in vivo imaging of extracellular vesicles in the kidney based on optical imaging. Chemiluminescence generated by inflammatory specific expression of MPO and detection of MPO enzyme activity and specific detection substance luminol in the kidney disease model formed fluorescence resonance energy transfer in extracellular vesicles of double-stained cells. Preliminary efficacy evaluation showed that the fluorescence intensity of the double-dyed extracellular vesicles system in this model is greater than that of the single-dyed extracellular vesicles. This method can be applied to the in vivo tracer of extracellular vesicles in the kidney, providing technical support for the treatment of extracellular vesicles in kidney disease and the study of drug delivery.

**CDYL IS A THERAPEUTIC TARGET FOR ACUTE KIDNEY INJURY BY REGULATION PYROPTOSIS**

Ting Xiang, Lingzhi Li, Wu Yiting, Ping Fu and Liang MA

West China Hospital, Sichuan University, Kidney Research Institute, Division of Nephrology, chengdu, P.R. China

**Background and Aims:** Pyroptosis as a necrosis type related to inflammation, is involved in various diseases, including acute kidney injury (AKI). Here, we report that Chromodomain Y-like (CDYL) is critical for pyroptosis regulation in AKI.

**Method:** Cisplatin-induced mouse model and cisplatin-induced TCMK-1 cell model of AKI were established, serum creatinine (Cr) and blood urea nitrogen (BUN) were measured to evaluate kidney function, and renal tissue lesions were observed by HE staining. The expression of gene/protein in relation to inflammation and pyroptosis were measured by qPCR and western blot. The CDYL was overexpression in mice by rapid injection of a volume of naked plasmid DNA solution (30 ug) through the tail vein 2 hours before intraperitoneal injection of cisplatin.

**Results:** The results indicate that CDYL was increased in cisplatin-induced and sepsis-induced AKI, and overexpression of CDYL in mice would significantly increase the expressions of NGAL, NLRP3, Caspase-1, GSDMD, IL-1β, MCP-1, TNFα and IL-6 (Fig. 1). RNA-seq shown that the genes were mainly enriched in fatty acid metabolic process when CDYL overexpression, and FABP4 was finally identified as the key downstream factor (Fig. 2). Overexpression of CDYL in cisplatin-induced AKI further aggravated renal injury compared with the model mice, as indicated by the increased inflammation and pyroptosis protein expression, and worse tissue architecture, while the knockout of FABP4 will attenuate the injury (Fig. 3). In addition, treatment with CDYL inhibitors could attenuate inflammation and pyroptosis in cisplatin-induced renal injury (Fig. 4) and cisplatin-stimulated TCMK-1 cells (Fig. 5).

**Conclusion:** CDYL played a role in inflammation and pyroptosis regulation in AKI. Inhibition of CDYL could suppress renal inflammatory response and pyroptosis, and improve kidney function via modulation of FABP4 expression. The results highlighted that CDYL might represent a potential therapeutic target against AKI.
DIFFERENTIAL ROLES OF REGNASE3 IN RESIDENT MACROPHAGE VERSUS TUBULAR EPITHELIAL CELLS IN THE HEALTHY OR POSTISCHEMIC KIDNEY
Chenyu LI, Julian Aurelio Marschner, Stefanie Steiger and Hans-Joachim Anders
Ludwig-Maximilians-Universität München, Germany

Background and Aims: Acute kidney injury (AKI) is a prevalent yet severe condition that occurs in clinical settings. The prognosis for AKI is poor, with many patients progressing to AKD, CKD, and even ESKD especially in those who were admitted to the ICU. RNA-binding proteins (RBPs) are a class of proteins that play a vital role in regulating gene expression and have been implicated in a wide range of diseases. Regnase3 is a member of the Regnase RBP family and has been shown to promote inflammation by increasing TNF in macrophages. Despite this knowledge, the full extent of the role played by Regnase3 in AKI remains unknown. Therefore, we hypothesized that Regnase3 plays a role in both macrophages and tubular epithelial cells, influencing inflammation and tubular repair in AKI.

Method: In order to investigate the role of Regnase3 in kidney injury, a series of genetically-modified mice were developed on the C57BL/6J genetic background. These mice included the paired box gene 8 (Pax8)-reverse tetracycline transactivator (tTA, Pax8rTtA), tetracycline resistance protein (TetO)-Cre (TetOCre), transgenic receptor activator of nuclear factor kappa-B (Rank)-Cre (RankCre), and Regnase3 floxed (Regnase-3fl/fl) mice. Using these genetically modified mice, we applied a range of experimental animal models to study the effects of Regnase3 on kidney injury, including unilateral kidney ischemia-reperfusion surgery with or without nephrectomy and nephrocalcinosis-related kidney injury. Additionally, we employed in vitro models utilizing primary cells to study Regnase3 on the cellular level. Furthermore, we utilized scRNA-seq and RNA-seq to investigate the underlying mechanisms of Regnase3's function.
Results: We conducted a thorough investigation and discovered that the Regnase3 is highly expressed in macrophages located within the kidney after AKI. The scRNA-seq showed the expression Regnase3 positively correlated with the phagocytosis, chemokines, and monocye maturation. Furthermore, Rank-Regnase3 mice suffered from more inflammation and kidney injury after AKI, characterized by an increase in CCR2 positive leukocyte infiltration. Additionally, in vitro experiments revealed that Regnase3 is involved in modulating macrophage behavior, acting as a regulator of macrophage polarization towards an M1 and M2 phenotype and influencing the capacity of cell migration. These findings indicate that Regnase3 is essential in the migration of macrophages after AKI, which contribute to both early phase inflammation and progression towards AKI-CKD. Next, we aimed to examine the role of Regnase3 in the context of renal tubule injury. We observed that Regnase3 is highly expressed in healthy renal tubules, but its expression is reduced following injury. Through in silico, in vivo and in vitro experiments, we found that Regnase3 controls early apoptosis, cell death, proliferation, and wound healing capacity of tubular epithelial cells. These effects contribute to kidney injury in postischemic kidneys. Additionally, we discovered that the deletion of Regnase3 provides protection against ischemic AKI (Figure 1). Mechanistically, Regnase3 targets pre-RNA and modulates alternative splicing. The deletion of Regnase3 provides protection against ischemic AKI (Figure 1). Mechanistically, Regnase3 targets pre-RNA and modulates alternative splicing. The deletion of Regnase3 provides protection against ischemic AKI (Figure 1). Mechanistically, Regnase3 targets pre-RNA and modulates alternative splicing. The deletion of Regnase3 provides protection against ischemic AKI (Figure 1). Mechanistically, Regnase3 targets pre-RNA and modulates alternative splicing. The deletion of Regnase3 provides protection against ischemic AKI (Figure 1).

Conclusion: In summary, our findings indicate that Regnase3 contributes to kidney injury in postischemic kidneys. However, the impact of Regnase3 is contingent upon the specific cell lineage in question. The Rank-Regnase3 leads to an exacerbation of kidney injury by increasing macrophage recruitment, whereas the Pax8-Regnase3 leads to an improvement in kidney injury through its effects on cell death and wound healing capacity of tubular epithelial cells. Therefore, the role of Regnase3 in kidney injury is dependent on the cell lineage, which ultimately determines the detrimental or beneficial impact on kidney injury.

DCR2 PROMOTES TUBULAR MALADAPTIVE REPAIR BY INHIBITING KETONE BODY–INDUCED FOXO3 SIGNALING AFTER ACUTE KIDNEY INJURY
Jia Chen1, Kehong Chen2, Liming Wang3, Jia Luo2 and Yani He2
1Daping Hospital, Army Medical University, Department of Nephrology, Chongqing, P.R. China
2Daping Hospital, Army Medical University, Department of Nephrology, Chongqing, P.R. China

Background and Aims: The proximal tubule has a capacity for repair after acute kidney injury (AKI), but this capacity is limited, especially in severe AKI. Tubular maladaptive repair after AKI leads to chronic kidney disease (CKD), even to end-stage renal disease (ESRD). However, the mechanism of maladaptive repair is not fully clarified, and there is a lack of effective treatment for AKI in clinic. Our previous study found that decay receptor 2 (DCR2), a trans-membrane receptor of tumor necrosis factor-related apoptosis inducing ligand (TRAIL), was specifically expressed renal tubules and did not have the ability of proliferation in AKI, suggesting DCR2 may be associated with maladaptive repair of tubular cells. This study aims to investigate the role and mechanism of DCR2-positive tubular cells in the repair of AKI.

Method: The DCR2-GFP lineage trace mice, KSP-cre Dcr2f/f mice (Distal tubular Dcr2 Conditional Knockout CKO) mice and Ggt1-cre Dcr2f/f (proximal tubular Dcr2 Conditional Knockout CKO) mice were constructed, and three AKI mouse models (moderate and severe ischemia-reperfusion injury and cisplatin-induced AKI) were used. Light microscopic examination of paraffin-embedded sections stained with haematoxylin and eosin, periodic acid–Schiff stain and Masson stain. Confocal analysis the co-expression of Dcr2-GFP and proximal tubular markers(AQP1, Villin), distal markers (AQP2), failed repair markers (Vcam, Dcdc2), proliferative markers (Ki-67, Edu, PCNA), Ki61, differentiated markers (pax2, sox9, s1x2), senescent markers (P16, P21, SA-β-gal), senescent phenotype (IL-6, TGF-β1) and fibrotic markers (a-SMA, collagen I, Fibronectin). And wild type (WT) mice and Dcr2 CKO mice were used to compare the degree of kidney injury, renal function and tubular repair after AKI. Furthermore, quantitative proteomics and bioinformatics analyzed the downstream molecules of Dcr2 in renal tissues from WT-AKI and Cko-AKI, and validated studies were done.

Results: In this study, we found decay receptor Dcr2 was highly expressed in renal tubules and associated with kidney damage in AKI patients and mouse models. Dcr2-GFP transgenic mice verified that Dcr2 was specifically expressed in proximal tubular epithelial cells (PTECs) after AKI. The levels of Scr, BUN and urinary and renal acute and chronic injury scores were significantly lower in Ggt1-cre Dcr2f/f -AKI than that of WT-AKI. Meanwhile, the proliferative markers, senescent markers and area of renal fibrosis and fibrotic markers expression was decreased in Ggt1-cre Dcr2f/f mice compared with WT. However, the above effects were not obviously improved in Ksp-cre Dcr2f/f mice after AKI. These results suggested that proximal tubular Dcr2 knockout alleviated kidney injury and promote tubular repair after AKI. Consistent with findings in vivo, Dcr2 promoted cell senescence and inhibited cell proliferation in hypoxia-reoxygenation and cisplatin-treated primary PTECs. Further quantitative proteomics and validated studies showed Hmgcs2, a key enzyme for ketone-body, was increased in Ggt1-cre Dcr2f/f mice compared with WT. And the levels of urinary and renal β-hydroxybutyrate (β-OHB) were higher in Ggt1-cre Dcr2f/f mice, suggesting Dcr2 affects the synthesis of β-hydroxybutyrate through regulating the expression of Hmgcs2. Inhibition or deletion of Hmgcs2 aggravated kidney damage and repressed renal repair, but administration with β-OHB rescued these phenomena. Subsequently, PTEC-specific Dcr2/Hmgcs2 double deletion decreased β-OHB levels, which...
inhibited FOXO3 signaling by regulating histone acetylation, thereby boosting tubular maladaptive repair after AKI.

Conclusion: DcR2 promotes maladaptive repair of tubular cells by regulating Hmgs2-induced β-OHB production, and β-OHB affects FOXO3 signaling by regulating histone acetylation. The findings suggest that DcR2/Hmgs2/ketogenesis/FOXO3 signaling mediates tubular maladaptive repair, and DcR2 could serve as a promising target for improving renal repair and AKI prognosis.

ACLARA: AN ON-LINE CALCULATOR TO ESTIMATE CREATININE CLEARANCE IN RATS
Isabel Fuentes-Calvo1, Eva María Baranda Alonso1, Noelia Diaz-Morales1, Oscar Pellicer-Valero2, Giampiero A. Massaro1, Alfredo G. Casanova3, María Paniagua-Sanchez1, Mykola Harvat1, José D. Martín1, Carlos Martínez Salgado1 and Francisco J. Lopez-Hernandez2

1Institute of Biomedical Research of Salamanca, Salamanca, Spain, 2Universitat de Valencia, IDAL, Burjasot, Valencia, Spain and 3Universidad de Salamanca, Salamanca, Spain

Background and Aims: Creatinine clearance (CICr) is a standard method for the measurement of glomerular filtration rate in rats. Recently, we developed ACLARA, an open and freely available neural network (NN)-based calculator of CICr in Wistar rats (http://idal.uv.es/aclara). By working solely on plasma creatinine concentration and body weight, ACLARA instantly and easily provides accurate CICr estimations with an identical concept to that underlying human glomerular filtration rate (GFR)-estimating formulae utility in the clinical setting. In addition to saving costs and time, ACLARA aligns with the 3Rs principles by providing a methodological refinement tool that reduces experimental animal stress derived from avoiding confinement in metabolic cages for individual, 24-hour urine collection. As a potential limitation, ACLARA was developed with data from Wistar rats. Accordingly, the aim of this study is to study ACLARA’s accuracy and utility in a different rat strain, namely the spontaneous hypertensive rat (SHR).

Method: In order to further validate the calculator, we used a dataset with 1,458 entries from unpublished experiments of AKI induced in Wistar and SHR male rats. Measured CICr (mCICr) was determined with a standard procedure, as we previously described [1], and estimated CICr (eCICr) was calculated using ACLARA. Calculator performance was assessed with the mean absolute error (MAE) and the Pearson product-moment correlation coefficient calculated as previously described [2]. Results of eCICr were compared with their corresponding mCICr values in the context of individual experiments.

Results: Our study reveals that ACLARA performs with reasonably high accuracy at CICr estimation in both Wistar and SHR rats as indicated by Pearson’s product-moment correlation coefficient (Crr) and MAE. The global Crr for the 1,458 measured versus estimated data values reaches 0.9, and a MAE of 0.18 mL/min. In general, estimated data provide identical results to measured data for individual experiments considered in the whole and, if anything, depict more congruent behavior. We interpret this improvement as the consequence of bypassing experimental errors introduced by the well-known discrepancies between the real and measured urinary flow in metabolic cages. Interestingly, ACLARA performs with accuracy through the range of ages and for all experimental conditions tested, including pharmacological treatments. Figure 1 shows a representative experiment in which measured and estimated data are compared holistically.

Conclusion: ACLARA is an easy-to-use and reliable tool to estimate creatinine clearance in SHR and Wistar rats from plasma creatinine concentration and body weight data. Validation for a second rat strain suggests a potential, wider application of ACLARA through laboratory rats, which needs to be further studied. In this sense, collaboration and use by independent investigators and recruitment of additional data sets from other laboratories is strongly sought to further adjust the calculator in order to enhance its accuracy, extend its applicability and improve its utility to the scientific community. This study was supported by Project PI21/01226, funded by Instituto de Salud Carlos III (ISCIII) and co-funded by the European Union, and a grant from the Consejería de Educación, Junta de Castilla y León (IES16020), Spain, co-funded by FEDER funds; and a grant from the Valencian Government with reference number CIAICO/2021/184. Noelia Diaz-Morales is recipient of a Juan de la Cierva-Formación postdoctoral contract (FJC2020-043205-I) funded by MCIN/AEI/10.13039/501100011033 and European Union “NextGenerationEU/PRTR”.

CITRATE SYNTHASE LACTYLATION PROMOTES THE TRANSITION FROM ACUTE KIDNEY INJURY TO CHRONIC KIDNEY DISEASE BY ACTIVATING NLRP3 INFLAMMASOME
Fang Yu, Yan Meng, Kehong Chen and Yani He

Daping Hospital, Army Medical University, Department of Nephrology, Chongqing, P.R. China

Background and Aims: Renal interstitial inflammation has been postulated to play a critical role in the acute kidney injury (AKI) to chronic kidney disease (CKD) transition. Recent studies have shown that protein lactylation caused by lactate accumulation can regulate chronic organ injury. The purpose of this study was to investigated the role and mechanism of protein lactylation in AKI-CKD transition.

Method: Severe renal ischemia-reperfusion(I/R) injury (severe AKI) was constructed by bilateral renal ischemia for 35min. The lactylation enhancer rotenone and the lactylation inhibitor oxamate were used to verify the effect of protein lactylation. Lactylated proteomics was used to detect the changes of lactylated proteins in renal cortex at different time points (day 0, 3, and 7), and the lactylated proteins related to kidney injury were screened for verification.

Results: The pathological staining results showed that the severe AKI mice were most severely injured at day 3, partially recovered at day 7, and developed renal interstitial fibrosis at day 28. The Serum creatinine (Scr) levels did not return to baseline at day 28 after I/R injury. The levels of lactate and protein

Figure 1: Comparison of measured and estimated CICr for a whole representative experiment. B, basal. D, day. G, group.
lactylation modification detected by Elisa and western blot analysis showed the same tendency as the above pathological injury, indicating that protein lactylation might contribute to the chronic transition of severe AKI. The renal injury score was significantly increased at day 3 and the percentage of renal interstitial fibrosis was significantly increased at day 28 after treatment with protein lactylation enhancer. The renal injury score was significantly increased at day 3 and the percentage of renal interstitial fibrosis was significantly increased at day 28 after treatment with protein lactylation enhancer. IL-1β and IL-18 were found to be the most significantly enhanced inflammatory cytokines in the blood of mice, and the NLRP3 inflammasome activation was significantly enhanced in renal tissue at 3 days. The in vitro results further confirmed these findings. We found that protein lactylation might activate the NLRP3 inflammasome, therefore leading to AKI-CKD transition. Meanwhile, lactylation inhibitor had a protective effect on AKI-CKD transition. Lactylated proteins were detected by lactylated proteomics analysis at day 0, 3 and 7 after I/R, and the enrichment of differential lactylated proteins was analyzed. The results showed that the differential proteins with significant difference mainly existed in the tricarboxylic acid cycle. One of them is citrate synthase (CS), a key rate-limiting enzyme in the tricarboxylic acid cycle. Citrate synthase lactylation level increased significantly on day 3 after AKI. Among the three lactylation sites of CS, the further screening revealed that CS-K370 is the most significant. We constructed mutations of CS-K370 lactylation sites to verify its effects on the enzyme activity and function. Results showed in hypoxia/reoxygenation (H/R) model for mice renal tubular epithelial cells (mRTECs), compared with control group, the enzyme activity of CS in K370T group (modified status) decreased significantly, while in K370R group (unmodified status) did not decrease significantly. Moreover, the lactation modification of CS-K370 can lead to the activation of NLRP3 inflammasome. The above results indicated that the lactylation of CS-K370 site inhibited the enzyme activity of CS and activated NLRP3 inflammasome.

**Conclusion:** Renal protein lactylation promotes activation of NLRP3 inflammasome, leading to AKI-CKD transition. Citrate synthase may be the key lactylated protein.

**ARDT AND ALK3 MEDIATE RENO PROTECTION AFTER ISCHEMIC PRECONDITIONING**

Gregor Christof Rapp 1, Michael Zeisberg 2 and Gunsmaa Nyamsuren 1

1 Göttingen University Medical Center, Department of Nephrology and Rheumatology, Göttingen, Germany and 2 Department of Nephrology and Rheumatology, Göttingen University Medical Center, Göttingen, Germany

**Background and Aims:** Ischemia and following hypoxia are a common cause of acute kidney injury (AKI). Strategies for prevention and treatment of AKI are limited. In several animal models, ischemic preconditioning (IPC) has been established as an effective intervention to prevent ischemic organ injury. An IPC protocol of ischemia and reperfusion mediates organ protection for a few hours. This first phase of organ protection is followed by a second, protective phase occurring after 24–48 h. The second phase, named second window of protection (SWOP), persists for 3–4 d. Mechanisms and transcriptional mediators during SWOP are mostly unknown. The aim of the underlying study was to investigate effectors and target genes during SWOP and to identify a potential pharmacological therapeutic target.

**Method:** 6–8-week-old C57BL/6 mice were undergoing an IPC intervention; five minutes of renal sinistra artery ischemia was followed by five minutes of reperfusion. This cycle was performed five times. Mice were sacrificed 2, 4, 8, 12, 25, 48, 72 h after IPC. Two additional groups of mice were pharmacologically preconditioned for 48 h with low dose FK506 and small molecule GPI1046. Analysis of murine kidneys were performed by SDS-Page and Western blot.

**Results:** The first phase after IPC (2–4 h) was characterized by an increasing expression of hypoxia inducible factor-1α (HIF1α); 48 h after intervention a significant increase of expression of aryl hydrocarbon receptor nuclear translocator (ARNT) and consecutive activin receptor-like kinase 3 (ALK3) was observed. Comparable induction of ARNT and ALK3 expression was obtained by pharmacological preconditioning with FK506 or GPI1046.

**Conclusion:** Affected by hypoxia, HIF1α activates transcriptional upregulation of ARNT 48 h after IPC. The increasing expression of ARNT, follows an increased ARNT homodimerization. ARNT homodimer binds to the palindromic E-box 5′-CACGTG-3′ of the proximal ALK3 promoter. By this it induces the expression of the renoprotective ALK3 during SWOP. The organ-protective effects of constitutively expressed ARNT during SWOP can be mimicked pharmacologically by administration of FK506 or GPI1046 and may be used as a future therapeutic target.

**Figure 1:** Schematic illustration of the multiple role of ARNT. Under hypoxia or xenobiotic stress, ARNT is the functional heterodimeric binding partner of aryl hydrocarbon receptor (AHR) or HIF-1α. In tubular epithelium, ARNT homodimers induce transcription of ALK3 and consecutively mediate regenerative and antifibrotic effects via the canonical pSMAD1/5/8-signaling cascade. MULTIDISCIPLINARY APPROACH TO STUDY THE BIOLOGICAL FUNCTION OF BBS10 IN THE PATHOGENESIS OF BARDET-BIEDEL SYNDROME (BBS)
Neha Gupta1, Giovambattista Capasso2 and Miriam Zacchia1
1University of Campania Luigi Vanvitelli, Italy and 2Biogem Scarl, Italy

Background and Aims: Bardet-Biedl Syndrome (BBS) is a rare inherited ciliopathy resulting in multiple organ dysfunctions, including chronic kidney disease (CKD). Although BBS is highly heterogeneous at genetic level, BBS10 is one of the significant causative genes, accounting for almost 30% of cases of BBS cases in western countries. Despite the recent progress in the ciliopathy field, there is still little information on the mechanisms underlying renal disease. To elucidate the pathomechanisms, we have broadened the study’s criteria into a combination of the in silico-in vitro approach.

Method: This study integrates the molecular dynamics (MD) simulations with the results of nine distinct (SIFT, SNAP2, PROVEAN, Align-GVGD, ConSurf, I Mutant, MuPro, PremPS, and Dynamut) in silico pathogenicity prediction tools. For in vitro studies we have used the inner medulla renal epithelial cells lacking Bbs10 (IMCD3-Bbs10-/- cells). MTT assay, Colony formation assay, Real time PCR, Western Blot and other experiments were performed using the cultured wild-type and IMCD3-Bbs10-/-cells. BBS10 interactors have been studied using Mass Spec, after pulling down BBS10-FLAG in renal epithelial cells expressing the protein, after transfection.

Results: Our in-silico results showed that six BBS10 missense variants (Ser191Leu, Cys19Gly, Ile342Thr, Cys371Ser, Ala417Glu, and Tyr613Cys) could be potentially deleterious. IMCD3-BBS10-/- cells lacking Bbs10 showed hyperproliferation, increased aerobic glycolysis and signs of mitochondrial dysfunction. Additionally, among BBS10 interactors in vitro, we found several proteins involved in cellular metabolism and mitochondrial-related function. Interestingly, Bbs10 depletion affected PINK1/Parkin signalling, leading to the disruption of mitochondria quality control.

Conclusion: This multi-disciplinary approach could open new avenues to study the extra-ciliary biological function of BBS10 in renal epithelial cells and providing novel clues into our understanding of disease pathomechanisms.

Background and Aims: Rhabdomyolysis is a pathological syndrome associated with massive and severe skeletal muscle injury. A common complication of rhabdomyolysis is acute kidney injury (AKI), a process that increases mortality of these patients. In rhabdomyolysis, myoglobin (Mb) is released from muscle cells and subsequently absorbed by the renal tubular epithelium causing a series of deleterious effects. TWEAK/Fn14 axis regulates renal inflammation and tubular cell death, pathogenic mechanisms involved in AKI. However, the role of this pathway in rhabdomyolysis-AKI has not been previously analyzed. In this study we analyzed the role of TWEAK/Fn14 axis in AKI associated with rhabdomyolysis and the AKI to chronic kidney disease (CKD) transition.

Method: We performed an experimental model of AKI associated to rhabdomyolysis by the intramuscular injection of 50% glycerol (10mg/Kg of weight) in Wild Type C57BL/6 (WT), TWEAK deficient (TWEAK -/-) and Fn14 deficient (Fn14 -/-) mice (male, 12 weeks old). In another set of
Injury markers of kidney function characterized by elevated serum creatinine (CRE) levels and reduced long-term consequences, mainly fibrosis and inflammation.

Results: Fn14 renal expression was increased at earlier stages of rhabdomyolysis, correlating with decline of renal function. In MCTs cells, Mb induced Fn14 expression in a time- and dose-dependent manner, whereas TWEAK expression remained unchanged. The use of general antioxidants (N-Acetylcysteine) or Nrf2 inducers (curcumin or Sulforaphane) reduced Mb-mediated Fn14 upregulation in vivo and in cultured renal cells, whereas the opposite effect was observed with the HO-1 inhibitor tin protoporphyrin IX (SnPP). Furthermore, MAPK p38 and ERK1/2 inhibitors, such as SB203580 and PD98059 respectively, diminished Mb effects on Fn14 expression. Moreover, Mb enhanced pro-inflammatory effects of TWEAK in vitro. In the animal model, we observed that genetic TWEAK or Fn14 deficiency ameliorated rhabdomyolysis-related loss of renal function, reduced histological damage, tubular cell death, lipid peroxidation, and decreased the expression of inflammatory mediators (Ccl2, Tnf, Il6, Tlr4 and Ccl5), tubular injury markers (Haver1 and Lcn2) and endothelial dysfunction (Edh1 and Icam1). TWEAK or Fn14 knockout mice also showed decreased long-term renal fibrosis (Collagen content and Fn14 expression) and inflammation (F4/80 macrophage infiltration and Ccl2 expression) 30 days after rhabdomyolysis induction. Treatment with a blocking anti-TWEAK monoclonal antibody maybe a potential therapeutic target to decrease harmful effects of rhabdomyolysis.

Conclusion: Our data suggest that TWEAK/Fn14 axis is involved in AKI-rhabdomyolysis, as well as in the transition from AKI to CKD. TWEAK/Fn14 may be a potential therapeutic target to decrease harmful effects of rhabdomyolysis.

ANTIOXIDANT PORPHYRIN-BASED NANOZYME WITH SINGLE RUTHENIUM FOR TREATMENT OF ACUTE KIDNEY INJURY
Shanshan Chen1, Qian Li1, Chong Cheng2 and Baihai Su1
1 West China Hospital, Sichuan University, Department of Nephrology, Chengdu, P.R. China, 2 College of Polymer Science and Engineering, Sichuan University, Chengdu, P.R. China

Background and Aims: Acute kidney injury (AKI) describes a sudden loss of kidney function characterized by elevated serum creatinine (CRE) levels and reduced urinary output. AKI patients have a high mortality rate, but limited treatment options are currently available. During the AKI progression, an excess of reactive oxygen species (ROS) leads to oxidative stress, which often results in cell damage and renal failure. Therefore, ROS scavenging has been considered a promising strategy for AKI treatment. Here we report a porphyrin-based nanozyme with single ruthenium (Por-Ru) as a ROS scavenger to cure AKI.

Method: The Por-Ru nanozyme was synthesised by one-pot synthesis. First, the 5,10,15,20-tetra(4-phenyl)-21H,23H-porphine (Por) was added to the solvent containing N, N-dimethylformamide. The RuCl3 was then introduced to form Ru-N coordinated porphyrin networks. We analysed the morphology and chemical structure using scanning electron microscopy (SEM) and X-ray photoelectron spectroscopy (XPS). We also tested its enzyme-mimicking abilities to scavenge ROS. The catalase-like (CAT) property was tested using a peroxide-titanium complex method, and the superoxide dismutase-like (SOD) property was tested using a •O2−- scavenging assay. In vitro, the protective effect of Por-Ru nanozyme against ROS damage was examined using the mouse tubular epithelial (TCMK-1) cell line. After biocompatibility evaluation, the therapeutic efficacy of Por-Ru nanozyme was investigated in glycerol-induced AKI mice.

Results: 1. Characterizations of Por-Ru nanozyme: The SEM image showed the Por-Ru nanozyme was spherical with an average diameter of 6-8 nm (Figure 1a). Meanwhile, the XPS revealed the presence of Ru and showed the detailed elemental components (Figure 1b). As shown in Figures 1c and d, the Por-Ru nanozyme had excellent CAT-like and SOD-like capabilities. Furthermore, the DPPH• assay confirmed the antioxidant property (Figure 1e). 2. Protective effect of Por-Ru nanozyme in vitro and in vivo: The results of cell counting kit-8 assay showed that Por-Ru nanozyme was not cytotoxic to TCMK-1 cells at concentrations ranging from 10 to 100 μg/mL. We further examined the cytoprotective effects of Por-Ru nanozyme against ROS damage. The flow cytometry results showed that the intracellular ROS level increased after treatment with H2O2, while the ROS level obviously decreased with the addition of Por-Ru nanozyme (Figure 2a, b). The protective effect of Por-Ru nanozyme against H2O2-induced apoptosis was also investigated. As shown in Figures 2c and d, the rate of cell apoptosis was significantly reduced with the addition of Por-Ru nanozyme. Before the in vivo experiments, the haemolysis assay (Figure 2c, d) showed that the Por-Ru nanozyme was synthesized to be less than 5% even at a dose of 200 μg/mL. Additionally, the in vivo toxicity assessment showed that Por-Ru nanozyme at test concentrations had no noticeable impacts on blood parameters, liver and kidney functions, and histopathology of major organs in normal mice. Then, we tested the therapeutic effect of Por-Ru nanozyme in AKI mice. As shown in Figures 2e and f, the CRE and blood urea nitrogen (BUN) levels of AKI mice treated with Por-Ru nanozyme were significantly lower than those of AKI mice group. Additionally, the results of haematoxylin and eosin (H&E) staining showed that many casts (marked as triangles) were observed in the kidney tissue of AKI mice, whereas no obvious damage area was found in AKI mice after the treatment of Por-Ru nanozyme.

Conclusion: Our findings demonstrate that the Por-Ru nanozyme has excellent anti-ROS enzyme-mimicking capabilities. In vitro experiments revealed that Por-Ru nanozyme alleviated ROS-induced cell apoptosis. In AKI mice, Por-Ru nanozyme effectively improved renal function and attenuated renal tissue damage. Taken together, Por-Ru nanozyme may become a novel agent for AKI treatment.
RIPK3 MEDIATES KIDNEY INJURY INDUCED BY A CYTOKINE STORM
Juan Guerrero Mauvecía, Diego Martín Sánchez, Ana Belen Sanz and Alberto Ortiz

Instituto de Investigación Sanitaria-Fundación Jiménez Díaz, Madrid, Spain

Background and Aims: Receptor-interacting protein kinase 3 (RIPK3) is traditionally involved in necroptosis, a regulated necrosis pathway which has been observed in diseases associated to cell death and inflammation. However, RIPK3 has been also associated to inflammatory responses independent of necroptosis. In previous studies we demonstrated that RIPK3 deficiency does not prevent renal injury but protects from inflammation in folic acid-induced AKI (FA-AKI), suggesting a proinflammatory role independently of cell death. In the present work, we aim to explore the role of RIPK3 in kidney injury and inflammation induced by a cytokine storm.

Method: Lipopolysaccharide (LPS) was used to induce cytokine storm-AKI in mice. For this, female 12- to 14-week-old wild type (WT), RIPK3-KO, MLKL-KO or NRLP3-KO C57BL/6J mice received a single intraperitoneal (i.p) injection of LPS 5 mg/kg or vehicle and were sacrificed 1h, 4h and 24 hours later. To generate chimera mice, WT and Ripk3-KO receptor mice were irradiated to deplete the autologous bone marrow (BM). BM was extracted from the femur and tibia of donor WT or Ripk3-KO mice, and 10^7 cells were transferred to irradiated receptor mice by intravenous injection. After 1 month, LPS-AKI was induced. Plasma was collected to assess kidney function. Kidneys were collected for RNA, protein studies, and histologic studies. Additionally, a WT group received 1.65 mg/kg of the necroptosis inhibitor Necrostatin-1 (Nec1) i.p. prior to LPS to evaluate the impact of necroptosis pathway. Liver, lungs and heart were also collected to assess the systemic inflammatory response. Additionally, cultured murine immortalized tubular MCT cells, and primary tubular cells, bone marrow dendritic cells (BMDC) and bone marrow derived macrophages (BMDM) isolated from WT and Ripk3-KO mice were studied. Cells were stimulated with 100 ng/ml LPS for 6h and RNA was studied. To analyze the impact of the inflammatory response on tubular cells, supernatants from LPS-stimulated BMDM and BMDC were collected and used to stimulate MCT cells. RNA expression was studied by RT-PCR and protein expression by Western Blotting.

Results: The kidney expression of RIPK3 mRNA and protein was upregulated in cytokine storm-AKI in mice, while Ripk3 deficiency improved survival and renal function, with less expression of proinflammatory cytokines and inflammatory infiltrate. Necroptosis did not seem to be implicated in cytokine storm-AKI, since neither Nec1 nor genetic MLKL ablation offered protection on renal function. Systemic inflammation in non-kidney organs was also milder with Ripk3 deficiency. In addition, inflammasome-related proteins were upregulated in cytokine storm-AKI, and this was reduced in Ripk3-KO mice. However, Nlrp3 deficient mice developed kidney injury and inflammation after LPS injection. Next, we explored the role of RIPK3 in BM-derived cells in cytokine storm-AKI by generating chimera mice. In this context, WT mice with Ripk3 deficient BM exhibited less inflammation and better renal function. This supports that RIPK3 from BM cells mediates kidney inflammation and injury during cytokine storm-AKI. In cultured cells, LPS induced RIPK3 expression in BMDMs but not in tubular cells, and RIPK3 mediated IL-6 expression in BMDMs but not in tubular cells. Moreover, IL-6 and conditioned media from LPS-exposed WT macrophages promoted proinflammatory responses in cultured tubular cells, that was partially ameliorated for RIPK3-KO LPS-macrophage conditioned medium.

Conclusion: In conclusion, RIPK3 mediates kidney injury and systemic inflammation induced by a cytokine storm independently of the necroptosis pathway. These results identify RIPK3 as a therapeutic target for renal inflammatory diseases.
Background and Aims: Direct tubular injury caused by several medications, especially chemotherapeutic drugs, is a common cause of AKI. Inhibition or loss of cyclin-dependent kinase 12 (CDK12) triggers a transcriptional elongation defect that results in deficiencies in DNA damage repair, producing genomic instability in a variety of cancers. Notably, 10-25% of individuals developed AKI after treatment with a CDK12 inhibitor, and the potential mechanism is not well understood.

Method: Here, we established a cisplatin-induced AKI mouse model with CDK12 knockdown mice and created stable in vitro models with CDK12 knockdown tubular epithelial cells. Cisplatin nephrotoxicity was induced by intraperitoneal injection of cisplatin (20 mg/kg). After 2 days following cisplatin treatment, blood and kidney tissues were harvested. Renal function and histology were evaluated. DDR, tubular apoptosis, cell proliferation were evaluated by immunofluorescence assays, real-time PCR, flow cytometer and western blot analysis. Notably, we performed single-molecule real-time sequencing (SMRT), a long-read sequencing platform, to identify the formation of novel transcripts involved in the above events.

Results: We found that CDK12 was downregulated in the renal tubular epithelial cells in both patients with AKI and murine AKI models. Moreover, tubular cell-specific knockdown of CDK12 in mice enhanced cisplatin-induced AKI through promotion of genome instability, apoptosis, and proliferative inhibition, whereas CDK12 overexpression protected against AKI. Using the single molecule real-time (SMRT) platform on the kidneys of CDK12\textsuperscript{RTEC−/−} mice, we found that CDK12 knockdown targeted Fgf1 and Cast through transcriptional elongation defects, thereby enhancing genome instability and apoptosis.

Conclusion: These data demonstrated that CDK12 knockdown could potentiate the development of AKI by altering the transcriptional elongation
Figure 2: Schematic illustration of the mechanism by which CDK12 knockdown aggravates cisplatin-induced AKI. In cisplatin-induced AKI, CDK12 knockdown could lead to DNA damage, apoptosis and abrogate cell proliferation via transcriptional elongation defects in Fgf1 and Cast.

defect of the Fgf1 and Cast genes, and more attention should be given to patients treated with CDK12 inhibitors to prevent AKI.

CHARACTERIZATION OF BRAIN DAMAGE AFTER ACUTE KIDNEY INJURY
Mickaël Bobot1, Sandrine Placier2, Chloé Samson3, Aurélie Prignon3, Liliane Louedec2, Marie-Christine Verpont1, Juliette Hadchouel2 and Pierre Galichon2
1Hospitals Academics De Marseille, Nephrology, Marseille, France, 2INSERM, Corakid, Paris, France and 3Sorbonne Université, LIMP, Paris, France

Background and Aims: Acute kidney injury (AKI) is a very common condition in inpatients. Severe AKI is frequently associated with by neurological disorders such as confusion, the mechanisms of which are poorly understood. We have shown in several animal models that chronic kidney disease is associated with impaired cognitive performance such as memory and increased permeability of the blood-brain barrier (BBB), related to the accumulation of uremic toxin indoxyl sulfate. The goal of these experiments was to highlight the influence of AKI on cerebral impairment in mice, particularly the BBB permeability, and to describe the mechanisms involved.

Method: We performed an AKI in C57/B6 WT mice, by unilateral nephrectomy and transient ischemia-reperfusion of the remaining kidney for 20 minutes (RIRI20 group) and compared them to two other groups: control mice and mice with unilateral ischemia-reperfusion without nephrectomy (IR20). Modified neurological severity score (mNSS) was performed daily. BBB permeability was assessed by quantification of the Evans Blue leakage in the brain and by cerebral 68Ga-DTPA TEP/CT imaging. Cerebral immunohistochemistry was performed to evaluate the neuro-inflammatory processes.

Results: Glomerular filtration rate at Day 1 was lower in AKI group compared to the control group 0.21 ± 0.26 vs. 0.94 ± 0.13 mL/min/100g b.w (p < 0.0001) and IR group: 0.75 ± 0.17 mL/min/100g b.w (p = 0.0007). Mice with AKI displayed a neurological impairment at day 1 and day 2 post-AKI, compared to control mice and IR20 mice, with mainly an impairment of the balance. Mean mNSS score at Day 1 was 2.6 ± 4.5 in AKI group, and 0.0 ± 0.0 in both the control and IR groups (p = 0.002). BBB permeability at Day 2 was higher in the AKI group than in the control group (p = 0.10) and the IR group (p = 0.0006) by Evans blue staining. Cerebral TEP imaging found similar results with increased BBB permeability in AKI mice to compared to control mice at D1 and D2 (p = 0.004 and p = 0.009, respectively). On immunohistochemistry, brains of mice after AKI displayed more astrocytosis and microglial activation compared to brains of control mice.

Conclusion: AKI in mice is specifically associated with early neurological damage, unlike renal ischemia-reperfusion alone, related to a BBB disruption in the first two days after AKI. AKI appears to induce astrocytosis and altered microglial phenotype, potentially due to increased neuroinflammatory processes following BBB disruption.

**INCREASED INFLTRATION OF LRG1+VCAN+LY6CHIGH MACROPHAGES ARE ESSENTIAL CONTRIBUTORS TO KIDNEY INJURY IN ADR MICE**

Qilin Chen, Yaru Jiang, Jinjie Zhong, Xiaojian Feng, Huimin Jiang, Junli Wan, Liping Peng, Mo Wang, Haiping Yang, and Qiu Li

P.R. China

**Background and Aims:** The ADR mouse model is a well-established rodent model for FSGS that can manifest with albuminuria. Resident macrophages are present in the tubulointerstitium of the kidney, and circulating macrophages can be recruited to the kidney in disease states. However, the presence of macrophages in glomeruli and the role of macrophages in podocyte injury in ADR mouse models remain unknown.

**Method:** Single-cell RNA sequencing comprehensively characterized the expression of macrophages in mice glomeruli. Eight-week-old male BALB/c mice were used to induce ADR model. Immunofluorescence was used to detect the changes of renal macrophages after injected with ADR at different time points. Transwell co-culture system were used to detect the effect of Lrg1+ Vcan+ Ly6Chigh macrophages on MPCS. HCH6-1, the FPR1 inhibitor were used to restrain ANXA1-FPR1 pathway.

**Results:** Totally 506 macrophages were sequenced and Lrg1Vcan Ly6Chigh macrophages were significantly increased in ADR induced nephrotic mice glomeruli (P < 0.01). The ligand receptor relationship between podocytes and macrophages were changed (P < 0.01, means±SD). Immunofluorescence demonstrated that macrophages are present in ADR glomeruli (P < 0.05). However, the temporal and spatial changes of macrophages in ADR glomeruli still need to be proved by further experiments. After co-culture of Lrg1Vcan Ly6Chigh macrophages and MPCS, the expression of nephrin in MPCS decreased (P < 0.05), which proved that macrophages can cause podocyte injury in ADR glomeruli. The ANXA1-FPR1 signaling pathway was activated and renal Lrg1 Vcan Ly6Chigh macrophage infiltration, albuminuria and renal injury were reduced in ADR+HCH6-1 group (all P < 0.05).

**Conclusion:** Lrg1 Vcan Ly6Chigh macrophages are recruited into glomeruli by activation of ANXA1-FPR1 signaling pathway and cause the damage of podocyte.

**MSC-DERIVED EXOSOMES PREVENT PERITONEAL FIBROBLAST TRANSDIFFERENTIATION IN PERITONEAL DIALYSIS-ASSOCIATED PERITONEAL FIBROSIS**

Fang Yu, Jia Chen, Xiaoyue Wang, Qingli Cai, Kehong Chen, and Yan He

Daping Hospital, Army Medical University, Department of Nephrology, Chongqing, P.R. China

**Background and Aims:** Peritoneal dialysis (PD) as a long-term renal replacement therapy is limited by peritoneal fibrosis. The purpose of our study was to identify the mechanism of mesenchymal stem cell-derived exosomes (MSC-Exos) in regulating the transdifferentiation of fibroblasts (FBs) to myofibroblasts (MFBS) in peritoneal dialysis-associated peritoneal fibrosis.

**Method:** The experimental mice were divided into 3 groups according to treatment: control group (Saline), peritoneal injury group (2.5% glucose peritoneal dialysate + LPS), and exosome group (2.5% glucose peritoneal dialysate + LPS + MSC-Exos). After six weeks of modeling, the parietal peritoneum was collected for histological analyses and transcriptomic analysis. We also verified the effects of MSC-Exos on fibroblasts in vitro and in vivo experiments referred to immunofluorescence, quantitative real-time RT–PCR assay, and western blotting analysis.

**Results:** First, tracing study of Dil-labeled exosome showed that exosomes can enter peritoneal tissue and peritoneal cells in vivo and in vitro. Our studies have found that MSC-Exos can alleviate peritoneal fibrosis in peritoneal injury mouse model. MSC-Exos treatment significantly decreased the expression of mouse peritoneal MFBS markers (α-SMA), while maintaining the phenotype of fibroblasts (Collagen I), indicating that MSC-Exos might inhibit the transdifferentiation of FBs to MFBS. The in vitro results further confirmed these findings. So we supported that MSC-Exos could alleviate peritoneal fibrosis by inhibiting the transdifferentiation of FBs into MFBS. Transcriptomic analysis results revealed that SPIC gene which is related to cell differentiation ranked first in the differential expression genes. The expression of Spi-C was significantly increased in peritoneal injury group, while were significantly down-regulated in MSC-Exos group. The results showed that Spi-C overexpression or knockdown had no significant impact in MSC-Exos group, while the transdifferentiation of FBs into MFBS greatly increased with Spi-C overexpression and significantly decreased with Spi-C knockdown in peritoneal injury group. The results indicated that Spi-C might be a critical molecule to promote peritoneal FBs to differentiate into MFBS in peritoneal injury models. Moreover, the mRNA sequencing results showed that miR-34b-3p is one of the main components of MSC-Exos, and it can specifically bind to SPIC gene sequence. The dual-luciferase reporter assay revealed that miR-34b-3p mimic significantly reduced the luciferase activity of Spi-C reporter. And miR-34b-3p mimics could down-regulate the expression of Spi-C, and the expression of Spi-C was not affected after miR-34b-3p inhibitor intervention. The above results suggested that MSC-Exos-derived miR-34b-3p could inhibit the transdifferentiation of FBs into MFBS by targeting Spi-C.

**Conclusion:** MSC-Exos-derived miR-34b-3p targeting Spi-C can alleviate peritoneal fibrosis by inhibiting the differentiation of subperitoneal mesothelial FBs in MFBS.

**GASDERMIN D DRIVES THROMBOTIC ANGIOPATHY-RELATED AKI BY ACCELERATING IMMUNOTHROMBOSIS AS WELL AS NEUTROPHIL-MEDIATED NECROINFLAMMATION AND INFARCTION**

Kanako Watanabe-Kusunoki1,2, Elmina Mammadova-Bach1, Andreas Linkermann1, Stefanie Steiger3, and Hans Joachim Anders1

1Department of Medicine IV, University Hospital, Ludwig-Maximilians-University Munich, Munich, Germany. 2Department of Rheumatology, Endocrinology, and Nephrology, Faculty of Medicine and Graduate School of Medicine, Hokkaido University, Sapporo, Japan. 3Department of Medicine, University Hospital, Ludwig-Maximilians-University Munich, Munich, Germany.

**Background:** Thrombotic microangiopathy (TMA) is a life-threatening complication in glomerulonephritis and immune mediated glomerular diseases. It is characterized by the formation of complement-coated platelet-fibrin thrombi, which induce tissue damage and organ failure.

**Method:** We investigated the role of Gasdermin D (GSDMD) in thrombotic microangiopathy-induced AKI using a mouse model of DcR2 knockout mice, compared with the wild group, there was no significant difference in the level of histone lactylation, while peritoneal thickness and the expression of markers of fibrosis markers (α-SMA, Collagen I, and Fibronectin) were significantly reduced.

**Conclusion:** Histone lactylation leads to peritoneal fibrosis induced by high glucose peritoneal dialysate by promoting PMSCs senescence. Histone lactylation may be a vital mechanism of peritoneal dialysis-related peritoneal fibrosis.

**HISTONE LACTYLATION ENHANCES PERITONEAL FIBROSIS BY INDUCING PERITONEAL MESOTHELIAL CELL SENESCENCE**

Fang Yu, Xiaoyue Wang, Qingli Cai, Yan He and Kehong Chen

Daping Hospital, Army Medical University, Department of Nephrology, Chongqing, P.R. China

**Background and Aims:** Peritoneal fibrosis (PF) is a serious complication limiting the application of peritoneal dialysis (PD). Histone lactylation has been recently found to increase with glycosylation and intracellular lactate levels, thereby mediating chronic organ damage. This study investigated the role and mechanism of histone lactylation in high glucose peritoneal dialysate-induced peritoneal fibrosis in mice.

**Method:** The PF mouse model induced by high glucose peritoneal dialysate was constructed by daily intraperitoneal injection of 4.25% glucose peritoneal dialysate combined with 40 mM Methylglyoxal for 2 weeks. We also used a lactylation enhancer (rotenone) and a lactylation inhibitor (oxamate) to limit the application of peritoneal dialysis (PD). Histone lactylation has been found to increase with glycosylation and intracellular lactate levels, thereby mediating chronic organ damage. This study investigated the role and mechanism of histone lactylation in high glucose peritoneal dialysate-induced peritoneal fibrosis in mice.

**Results:** In the PF group, the results of Masson staining and immunohistochemistry revealed increased peritoneal thickness and expression of fibrosis markers (α-SMA, Collagen I, and Fibronectin) and senescence markers (P16, P21, and DcR2) compared to the control group. We found that lactate and glycosylation levels were significantly higher in the PF group compared to the control group, and further immunoprecipitation results also showed enhanced levels of histone lactylation modifications in the PF group. We further found that the 101/1 of lactylation modification of H3K18a site increased significantly, suggesting that H3K18a site may play an important role in promoting PF. Similarly, in vitro, we verified that peritoneal mesothelial cells (PMCS) exhibited increased levels of lactate and lactylation in response to stimulation by high glucose, while we found an increasing expression of cell senescence phenotype (P16, P21, and DcR2) and senescence-associated cytokines secretion (IL-1β, IL-6, and TNF-α). By enhancing or inhibiting lactylation, we found that PMCS senescence was significantly enhanced in the lactylation-enhanced group, while the lactylation-inhibited group alleviated PF. Senescence induced by high glucose peritoneal dialysate. In the PF model of DcR2 knockout mice, compared with the wild group, there was no significant difference in the level of histone lactylation, while peritoneal thickness and the expression of markers of fibrosis markers (α-SMA, Collagen I, and Fibronectin) were significantly reduced.

**Conclusion:** Histone lactylation leads to peritoneal fibrosis induced by high glucose peritoneal dialysate by promoting PMSCs senescence. Histone lactylation may be a vital mechanism of peritoneal dialysis-related peritoneal fibrosis.
Background and Aims: Cholesterol crystal embolism (CCE) is a life-threatening complication of advanced atherosclerosis, in which CC can trigger clot formation, arterial occlusion, acute kidney injury (AKI), and ischemic infarction. Neutrophils play a role in this process by driving arterial crystalline immunothrombosis and undergoing regulated necrosis in necroinflammation surrounding ischemic kidney infarcts. In this study, we hypothesized that Gasdermin D (GSDMD) contributes to the pathogenesis of CCE by amplifying these processes.

Method: We injected CC (20 mg/kg) into the left kidney artery of wildtype (WT) or Gsdmd-knockout (KO) mice to induce CCE. The mice were sacrificed after 24 hours. Kidney injury was assessed through glomerular filtration rate (GFR), histological analysis using periodic acid-Schiff and TUNEL staining as well as assessment of infarct size and arterial obstruction via triphenyltetrazolium chloride and alpha-smooth muscle actin/fibrin staining, respectively. Neutrophils (Ly6G+) and mature neutrophils (Ly6G+ CD101+) were analyzed in several organs by flow cytometry. The presence of neutrophil extracellular traps (NETs) in kidney was evaluated by staining for citrullinated histone 3 (CitH3) and flow cytometry analysis of Ly6G+ CitH3+ neutrophils. Interventional studies using disulfiram, a GSDMD inhibitor, administered via intraperitoneal injection (50 mg/kg) to WT mice either 4 hours prior or 3 hours following CCE induction, followed by sacrifice and analysis after 24 hours. In vitro, healthy human neutrophils were stimulated with CC in the presence or absence of pretreatment with disulfiram, and the levels of IL-1 beta and lactate dehydrogenase (LDH) were evaluated in the culture supernatant.

Results: WT CCE kidneys showed increased expression of Gsdmd in peritubular cells as determined by immunohistochemical analysis, as well as an increased expression of cleaved Gsdmd by immunoblot analysis compared to WT control kidneys. Baseline levels of GFR and the number of both total and mature neutrophils were comparable in both groups under normal conditions. Compared to WT mice, Gsdmd-KO mice were partially protected from sudden GFR decline, tubular injury, kidney cell death, and kidney infarction following CCE. Arterial obstruction was significantly reduced in Gsdmd-KO mice following CCE. Gasdermin-deiciency reduced the number of mature neutrophils in bone marrow, spleen, and blood in comparison to WT mice. The amount of NETs in kidney exhibited a significant reduction in Gsdmd-KO mice. Consistently, preemptive and therapeutic treatment with disulfiram significantly reduced sudden GFR decline and kidney infarct size in WT mice compared to vehicle-treated controls. Blood and kidney neutrophils, as well as blood and kidney NETs were significantly reduced in WT CCE mice with disulfiram preemptive and therapeutic treatment in comparison to respective vehicle controls. In vitro, CC induced the release of IL-1beta and LDH from healthy human neutrophils, which disulfiram suppressed in a dose-dependent manner.

Conclusion: The deficiency and pharmacological inhibition of GSDMD alleviate crystal clot formation, AKI, and ischemic infarct growth following CCE via suppressing neutrophil recruitment, maturation, and NET formation. Thus, neutrophils significantly contribute to immunothrombosis and ischemic kidney infarction.

Z-DNA BINDING PROTEIN 1 AGGRAVATED THE SEPSIS-INDUCED ACUTE KIDNEY INJURY VIA PANOPTOSIS
Ruilian You, Jiataog Xu, Yixin MA, Xiaoxiao Shi, Zhu Huadong and Limeng Chen
Peking Union Medical College Hospital, Beijing, P.R. China

Background and Aims: Sepsis-induced acute kidney injury (SI-AKI) is a severe complication of critical patients with high morbidity and mortality. Apoptosis, pyroptosis, and necroptosis, regulated by a common pathway - PANoptosis, play essential roles in SI-AKI without the clarified mechanisms.

Method: We first established the SI-AKI model by intraperitoneal injection of the lipopolysaccharide (LPS) (O111:B4) in the C57B/L6J mice with increased Serum creatinine (Scr), blood urea nitrogen (BUN), and kidney injury biomarkers (NGAL, KIM-1) in renal tissue. The expression of crucial molecules in PANoptosis were examined by quantitative real-time PCR (qPCR) and Western blotting. RIPK1 inhibitor-necrostatin-1 (Nec-1) (1.65mg/kg) and pan-caspase inhibitor- Emricasan (10mg/kg) were further employed to mice with LPS. Potential interacting proteins of panoptosome were detected by co-immunoprecipitation. We also analyzed the methylation level of ZBP1 in cell-free DNA among sepsis-non-AKI and SI-AKI patients.

Results: The expression of crucial molecules in PANoptosis, including IL-1beta, mixed lineage kinase domain-like (MLKL) (0.67 vs. 0.41, P = 0.014), protein kinase 1 (RIPK1) (1.07 vs. 0.72, P = 0.002), cleaved-caspase 3 (1.13 vs. 0.59, P < 0.001), and FAS-associated death domain protein (FADD) (0.78 vs. 0.43 P < 0.001) elevated in the SI-AKI group. Z-DNA binding protein 1 (ZBP1), a typical sensor of PANoptosis, is dramatically activated in the SI-AKI mice. Co-immunoprecipitation showed that caspase 8, ZBP1, peptidoglycan recognition protein 1 (pglyrp1), and RIPK1 are potential components of PANoptosome. Nec-1 and Emricasan could attenuate the LPS-induced increases in the concentrations of BUN and inflammatory cytokine (TNF-a and IL-6), as well as the methylation level of ZBP1 in cell-free DNA decreased in SI-AKI patients versus sepsis-none-AKI (P = 1.60E-06).

Conclusion: ZBP1 exacerbated SI-AKI via activating PANoptosis with the potential PANoptosome of ZBP1, caspase 8, pglyrp1, and RIPK1.
PERICYTE AND CXCL12 PLAY CRUCIAL ROLE IN THE RECOVERY OF ACUTE KIDNEY INJURY
Yu-Han Shao1, Yu-Hsiang Chou1,2, Yung-Ming Chen2,3 and Shuei-Liong Lin1,2

1National Taiwan University College of Medicine, Graduate Institute of Physiology, Taipei, Taiwan, Rep. of China, 2National Taiwan University Hospital, Renal Division, Department of Internal Medicine, Taipei, Taiwan, Rep. of China and 3National Taiwan University Hospital Bei-Hu Branch, Renal Division, Taipei, Taiwan, Rep. of China

Background and Aims: Pericytes are mesenchyme-derived perivascular cells attached to the abluminal surface of capillaries as well as the major origin of myofibroblasts in the animal model of unilateral ureteral obstruction (UOO) and ischemia-reperfusion injury (IRI). Although previous studies reported that myofibroblasts may be beneficial during acute kidney injury (AKI) via growth factor secretion, reconstitution and stabilization of the collagen framework for tubular cell regeneration, lack of solid evidence and definite mechanism make the role of pericyte/myofibroblast in AKI remain controversial.

Method: To clarify this, we used platelet-derived growth factor receptor β (PDGFRβ)-specific antibody following AKI in C57BL/6 mice to inhibit pericytes. In the meantime, We used Gli1-CreERT2;Cxcl12fl/fl genetically modified mice to conditionally knockout CXCL12 specifically in pericytes before IRI.

Results: The expression of PDGFRβ on pericytes increased after IRI. In group of administration of PDGFRβ antibody, proliferation and transition to myofibroblasts of pericytes were inhibited. Inflammation became worse and renal recovery was impeded after AKI. The chemokine stromal cell-derived factor-1 (SDF-1) which is also known as the C-X-C-type chemokine CXCL12 decreased as well. Furthermore, we demonstrated that CXCL12 was secreted mainly by pericytes and its receptor CXCR4 was expressed on tubular cell during IRI by in situ hybridization. When knockout of CXCL12 was performed before IRI, the renal microvascular rarefaction was noted after AKI and the recovery of renal function was impaired. Renal tubular cell proliferation decreased and apoptosis increased as well.

Conclusion: In summary, these findings demonstrated that pericytes contribute to renal repair after IRI through CXCL12 secretion.
Figure 1: Anti-PDGFβ Ab inhibited pericyte–myofibroblast transition and tubular regeneration after IRI. (A) Representative images showed αSMA+ cells of the kidneys at day 5 after IRI with or without anti-PDGFβ antibody administration. Bar chart showed the numbers of αSMA+ cells. (B) Representative images showed Ki67+ cells of the kidneys at day 5 after IRI with or without anti-PDGFβ antibody administration. Bar chart showed the numbers of Ki67+ cells. Scale bar, 50 μm. Original magnification ×200. n = 5 for each group. Data were expressed as the mean ± SEM. *P < 0.05, **P < 0.01, ***P < 0.001 by Student’s t-test.

IMMUNE LANDSCAPING IN RHABDOMYOLYSIS INDUCED ACUTE KIDNEY INJURY IDENTIFIES SENESCENCE AS A POTENTIAL TARGET
Snigdha N Rao1, Margot Zahm2, Marie Buleon1, Audrey Casemavou1, Stanislas Faguer3, Guylene Feuillet1, Jason Iacovoni1, Olivier Joffre2, Ignacio Gonzalez-Fuentes1, Frédéric Martins1, Elodie Riant1, Alexia Zakaroff-Girard1, Joost Schanstra4, Jean Sébastien Saulnier Blache5 and Julie Belliere3
1I2MC Inserm U1297 - Institut des maladies métaboliques et cardiovasculaires, Toulouse, France and 2Infinity Inserm U1291, Toulouse, France
Background and Aims: Worldwide, acute kidney injury (AKI) has an incidence of 13.3 million cases per year leading to 1.7 million deaths. Rhabdomyolysis (RM) accounts for 10% of the AKI cases, and frequently occurs due to falling (often in elderly), crush syndrome or exposure to drugs. By causing skeletal muscle damage, RM leads to a release of muscle contents such as myoglobin into the circulatory system and trigger renal sterile inflammation. The role of macrophages in driving inflammatory phase of RM-AKI lesions and fibrosis-related prognosis has been reported but both the role of other immune cells and the macrophage heterogeneity in RM-AKI still lack detail. The aim of this study was to describe renal immune cell recruitment and more specifically the mononuclear phagocytic cell (MPC) population (macrophages, monocytes and dendritic cells) during RM-AKI through single cell RNA sequencing (scRNA-seq) in mice.
Method: Two-month-old C57BL/6J male mice were administered intramuscularly saline (control) or 50% glycerol for induction of RM. Forty-eight hours later mice were sacrificed, kidneys were collected and dissociated and CD45 live cells were sorted. Single cell cDNA libraries were prepared, and sequencing was performed according to the 10X Genomics protocol. Creatinine phosphokinase and blood urea nitrogen were quantified to validate muscle injury and renal function respectively. A combination treatment of dasatinib and quercetin (DQ) protocol was performed according to the 10X Genomics protocol. Creatinine phosphokinase and blood urea nitrogen were quantified to validate muscle injury and renal function respectively. A combination treatment of dasatinib and quercetin (DQ) protocol was performed with and without RM-AKI.
Results: scRNA-seq of CD45+ renal cells revealed the existence of 7 immune cell clusters with macrophages and monocytes as the most highly recruited cells in RM-AKI condition, indicating a major change in the MPC population. Specific clustering of MPCs divulged 10 clusters (8 macrophages, 1 monocyte and 1 dendritic cell cluster) revealing a higher heterogeneity of this population compared to what was previously observed by flow cytometry. Trajectory, pseudotime and KEGG pathway enrichment analyses disclosed a unique cluster highly expressing Stat5b and present in both control and RM-AKI condition where 164 cells were observed in control condition which expanded to 333 cells in RM-AKI condition. This unique cluster was characterized by a bimodal expression of MHCIImarkers and a downregulation after RM-AKI suggesting a transcriptional reprogramming. Cellular senescence was observed to be a predominant pathway in this unique cluster. Senolytics were identified as a possible pharmacological target based on pathway analysis. DQ protocol accompanied with an improvement of kidney function as well as an attenuation of MPC phenotypic modifications.
Conclusion: This study revealed the MPC diversity in RM-AKI through immune landscaping, trajectory and pathways in RM-AKI in mice. A unique cluster associated with possible reprogramming of macrophages was identified. Senolytics were established as a potential nephroprotective strategy in RM-AKI.

CYCLIN D1 AMELIORATES ISCHEMIA/REPERFUSION-INDUCED ACUTE KIDNEY INJURY
Yuliang Huang, Junzhe Chen, Xiaofei Shao, Jinxiang Li and Ying Tang
The Third Affiliated hospital of Southern Medical University, Department of Nephrology, Guangzhou, China., P.R. China
Background and Aims: Acute kidney injury (AKI) is a life-threatening condition. The absence of oxygen during the acute ischemic phase would disturb energy metabolism and cause kidney tubular epithelial cell damage. Fatty Acid Oxidation (FAO) is the main source of energy production of renal proximal tubular epithelial cells. Timely promoting FAO, increasing supplies of energy, and promoting cell proliferation are essential to improve kidney injury, but there is no clinically recognized effective treatment for this. Cyclin D1 (CCND1), a member of the cell cycle family, plays a vital role in cell proliferation. Our previous study found that CCND1 improved AKI accompanied with increased fatty acid oxidation. Therefore, we investigated the role and molecular basis for CCND1 involvement in fatty acid oxidation of AKI.
Method: CCND1 was evaluated in AKI in human kidney proximal tubular epithelial cells (HK-2 cells) and male C57BL/6j mice (wild type). The protective role of CCND1 in AKI was investigated in a mouse model of ischemia-reperfusion AKI treated by ultrasound-microbubble-mediated kidney-specifically transferring CCND1-expressing plasmids in male C57BL/6j mice (wild type). Eight-week-old male C57BL/6j mice (wild type) were subjected to bilateral renal artery occlusion for 30min followed by 24h of reperfusion. We evaluated FAO, proliferation, and autophagy in vitro
and in vivo. In addition, we evaluated the concentrations of blood urea nitrogen and creatinine, evaluated kidney ultrastructure and so on.

**Results:** In vivo studies had shown that activation of CCND1 can prevent AKI-induced lipid accumulation, kidney tubule injury and kidney function declined after ischemia-reperfusion injury. Compared to test control, the treatment significantly (p < 0.05) lowered the concentrations of blood urea nitrogen and creatinine. Kidney specific overexpression of CCND1 promoted FAO, promoted proliferation and reduced apoptosis. Mechanistically, CCND1 activated the AMPK pathway, which increased the expression of phosphorylation AMP activated protein kinase (p-AMPK) and upregulated FAO. On the contrary, inhibiting the expression of CCND1 exacerbated impairment of FAO and disturbed energy metabolism.

**Conclusion:** Thus, CCND1 improved FAO and reduced lipid accumulation via active AMPK pathway in kidney proximal tubular epithelial cells (PTECs). Hence, reconstruction of the expression of CCND1 may be a novel therapeutic strategy for treating AKI.

![Figure 1: Cyclin D1 ameliorates acute kidney injury by improving fatty acid oxidation.](image)

Eight-week-old male C57BL/6J mice (wild type) were subjected to bilateral renal artery occlusion for 30min followed by 24h of reperfusion to investigate the effect of Cyclin D1 in ischemia/reperfusion-induced acute kidney injury. (a) Western blot analysis of kidney injury molecule (KIM-1), proliferating cell nuclear antigen (PCNA), Cyclin D1 (CCND1), phosphorylation AMP activated protein kinase (p-AMPK), AMP-activated protein kinase (AMPK), peroxisome proliferator activated receptor-α (PPAR-α) in the kidneys (n = 3). β-Actin was used as the loading control. (b) Blood urea nitrogen (BUN) and creatinine (Cr) concentrations were measured in WT mice. (c) Representative images of periodic acid-schiff (PAS) staining. Representative images of immunohistochemistry staining of Cyclin D1 (CCND1) and kidney injury molecule (KIM-1). Representative images of immunofluorescent staining were used to evaluate the expression of proliferating cell nuclear antigen (PCNA; green) and 5′-bromo-2′-deoxyuridine (BrdU; green) in the kidneys. Representative images of Oil red O (ORO) staining.
MAGNESIUM DEFICIENCY ABROGATES THE RENOPROTECTIVE EFFECT OF DPP-4 INHIBITOR ON CISPLATIN-INDUCED KIDNEY INJURY

Takamasa Iwakura1, Chiemi Ema1, Tomoyuki Fujikura1, Hirotaka Fukasawa2 and Hideo Yasuda1

1Hamamatsu University School of Medicine, First Department of Medicine, Hamamatsu, Japan and 2Iwata City Hospital, Department of Nephrology, Iwata, Japan

Background and Aims: Cisplatin is an effective chemotherapeutic agent, but often induces acute kidney injury (AKI). Magnesium (Mg) deficiency is often found in cancer patients, and the nephrotoxicity of cisplatin is exacerbated under Mg deficiency [1]. We previously reported the potential of Dipeptidyl peptidase-4 (DPP-4) inhibitor to attenuate cisplatin nephrotoxicity in rats and diabetic cancer patients [2, 3]. However, it remains to be investigated whether DPP-4 inhibitor can preserve its renoprotective effect under Mg deficiency. The purpose of this study was to examine whether DPP-4 inhibitor can prevent cisplatin-induced AKI even under Mg deficiency.

Method: Sprague Dawley rats received Mg-deficient diet for 7 days to induce Mg deficiency. AKI was induced in rats by injecting cisplatin intravenously. Oral administration of a DPP-4 inhibitor, once a day, was started 1 day before injecting cisplatin. Mg sulfate was once injected intraperitoneally just before injecting cisplatin to correct Mg deficiency (Fig. 1A). By using our previous cohort data [3], we divided diabetic cancer patients treated with high-dose cisplatin (> 50 mg/m2)-containing regimens into 4 groups according to the use/unused of Mg sulfate or DPP-4 inhibitor. The change of estimated glomerular filtration rate (eGFR) within 2 weeks after cisplatin treatment was compared between the groups.

Results: At the peak of AKI (day 5), Mg sulfate supplementation significantly attenuated the increase of blood urea nitrogen (BUN), and combination of Mg sulfate and DPP-4 inhibitor further suppressed the increase of BUN as compared to rats received only cisplatin. However, DPP-4 inhibitor alone did not attenuate the increase of BUN under Mg deficiency (Fig. 1B). The result of serum creatinine (sCr) was consistent with that of BUN (Fig. 1C). This effect was associated with a reduced renal cell death as evaluated with the terminal uridine nick-end labeling (TUNEL)+ cells (Fig. 1D). The change of eGFR was significantly less in the patients treated with both of DPP-4 inhibitors/Mg supplementation, compared to those without DPP-4 inhibitors/Mg supplementation. The effect was not found in patients with either DPP-4 inhibitor alone or Mg supplementation alone as compared to those without DPP-4 inhibitor/Mg supplementation (Fig. 2).

Conclusion: Our results suggested that Mg deficiency must be corrected to exert the renoprotective effect of DPP-4 inhibitor on cisplatin nephrotoxicity. The molecular mechanisms underlying this phenomenon remain to be defined.

Gasdermin D is required for control of necroptotic cell death in AKI
Wulf Tonnus, Anne Brucker and Andreas Linkermann
Technische Universität Dresden, University Hospital GGC, Medical Clinic 3, Dresden, Germany

Background and Aims: Contradicting previous reasoning, it is now established that necrotic rather than apoptotic cell death pathophysiologically drives acute tubular necrosis during AKI. Whereas involvement of necroptosis and ferroptosis has been demonstrated by various groups, the role of pyroptosis, a highly immunogenic form of cell death requiring proteolytic activation of gasdermin protein family members, remains uncertain upon AKI. Thus, we aimed to investigate the role of pyroptosis and its mechanism of action in AKI.

Method: We set to detect gasdermin D (GSDMD) expression in murine renal samples after ischemia/reperfusion injury (AKI) by immunohistochemistry. Furthermore, we investigated GSDMD-deficient mice in IRI and cisplatin-induced AKI. To conclude on mechanisms, we isolated fresh murine renal tubules and measured LDH release over time. We generated MLKL/GSDMDdko mice to investigate the interplay of these caspase-dependent forms of regulated necrosis in AKI.

Results: After IRI, we detected a specific GSDMD signal in areas surrounding necrotic tubules, whereas no such signal could be detected within necrotic areas. Whereas interference with other forms of regulated necrosis leads to reduced injury, GSDMD-deficient mice demonstrated higher levels of serum creatinine and urea as well as more severe tubular injury compared to wildtypes. In line with the findings of immunohistochemistry, we only found GSDMD protein expression in whole kidney lysates but not isolated renal tubules; and no difference in spontaneous cell death propagation was detectable. Co-deletion of MLKL (effector protein of necroptosis) reversed the sensitization to AKI by GSDMD-deficiency. These results could be reproduced in cisplatin-induced AKI.

Conclusion: Here, we found an unexpected protective role for GSDMD, the effector protein of pyroptosis, in two different models of AKI. Mechanistically, our studies indicate the effect of GSDMD to function outside the tubular compartment, specifically surrounding areas of tubular necrosis. These infiltrating innate immune cells appear to interfere with tubular necroptosis in a non-cell autonomous manner. Alongside with these mechanistic insights, our data urge caution when inhibition of pyroptosis is therapeutically considered.

Identification of an Antibiotic-Treated Mouse Model to Study the Gut-Kidney Axis
Consiglia Longobardi1,2, Antonio Miele1, Mariavittoria D’acicerno2, Ines Simeone3,4, Michele Ceccarelli5, Giovambattista Capasso5 and Anna Iervolino2,6
1University of Campania “Luigi Vanvitelli”, Department of Mental, Physical Health and Preventive Medicine, Naples, Italy, 2Ca.re.BioX “Campus Regi Biologia”, Ariano Irpino (AV), Italy, 3University of Naples “Federico II”, Department of Electrical Engineering and Information Technology, Naples, Italy, 4Center for Genomic Science of IIT@SEMM, Naples, Italy, 5BIOGEM Institute of Molecular Biology and Genetics, Ariano Irpino AV, Italy and 6University of Campania “Luigi Vanvitelli”, Department of Translational Medical Sciences, Naples, Italy

Background and Aims: Microbiota and its modulation could influence several physiological functions, and there is growing interest in it as a cutting-edge research topic in the field of renal diseases. According to the literature, germ-free (GF) mice are the gold-standard animal model for studying the correlation between the changing microbiota and the effects in the host. Unfortunately, their generation and maintenance are often unfeasible and costly, and the lack of microbiota could influence the circulating levels of amino acids, thus affecting kidney growth. This study aims to identify a more advantageous mouse model, specifically an antibiotic-treated one, that exhibits a strong reduction of the gut microbiota without compromising the kidney functionality.

Method: Five-six weeks old C57/BL6 male mice were randomly divided into 5 groups: Group 1 (Tr1) received a cocktail containing ampicillin, gentamicin, metronidazole, neomycin (1mg/mL each) and vancomycin (0.5 mg/mL) by oral gavage for 10 days; Group 2 (Tr2) received drinking water (DW) supplemented with ampicillin (1 mg/mL) neomycin (1 mg/mL), metronidazole (1 mg/mL) and vancomycin (0.5 mg/mL) for 14 days; Group 3 (Comb3) was treated with amphotericin-B (0.2 mg/mL) by oral gavage for 3 days followed by an antibiotic cocktail composed by vancomycin (10 mg/mL), neomycin (20 mg/mL), metronidazole (20 mg/mL) and amphotericin-B (1 mg/mL) administrated by oral gavage and ampicillin (1 mg/mL) provided in DW for 7 days; Group 4 (Comb4) was treated with a combination of ampicillin, neomycin, metronidazole and vancomycin (40mg/mL each) both by oral gavage and DW. Control Group (Ctr) received milliQ water only. Fecal DNA was used to assess the reduction of the intestinal microbiota by the 16S gene rRNA sequencing, and intestinal permeability was determined both in vivo by FITC-dextran and by measuring the expression of Zonulin-1 (ZO-1) on intestine sections. To verify the kidney integrity after treatment, renal morphology and fibrosis were evaluated by multiphoton microscopy, while transdermal measurement of GFR occurred by using MediBeacon device.

Results: Apart from Tr1, with the less percentage of microbiota depletion, the rest of antibiotics cocktails exhibited a significant microbiota reduction. Data regarding intestinal permeability in vivo by FITC-dextran were consistent with hematolysin-esin staining and revealed a reduced expression of ZO-1 in all antibiotics-treated groups versus Ctr, confirming that microbiota has been depleted as expected. In all the experimental groups, particularly Tr2, urine/serum parameters reestablished at Ctr levels after recovery and only Comb4 showed signs of fibrosis. The low intragroup variability and the homogeneous decrease of the most abundant phyla, as well as renal physiology evaluation, point to Tr2 as the most promising antibiotics cocktail among the tested ones.

Conclusion: The potential of our study lies in the feasibility to have a manageable mouse model to perform studies on the gut-kidney axis. In particular, it will be specifically used for the evaluation of fecal microbiota transplant (FMT) with feces of patients affected by kidney diseases, enabling us to determine whether intestinal dysbiosis may impair the kidney functionality. However, the characterized mouse model might be employed to assess the effect of the FMT from patients with renal pathologies not only on kidneys but also at systemic level.

The Molecular Effect of SGLT2i on the Autophagy Pathway in Type II Diabetes Mellitus and Its Vascular Complications
Ofrir Ertracht1,2,3,4, Raneen Saad1, Hagar Tadmor5, Farid Nakhoou6, and Nakhoul Nakhoou6
1Cardio-Vascular Research Lab, Cardiology, Israel, 2English, Israel, 3Cardio-Vascular Research Lab, Cardiology, Nahariya, Israel, 4Azriely Faculty of Medicine, Israel, 5Baruch Padeh Poriya Medical Center, Diabetes & Metabolism lab, Israel, 6Cardio-Vascular Research Lab The Galilee Medical Center, Cardiology, English, Israel and 7Baruch Padeh Poriya Medical Center, Ophthalmology, Israel

Background and Aims: Type II Diabetes mellitus (T2DM) is a severe metabolic disorder characterized by chronic hyperglycemia and its subsequent glucose toxicity that lead to irreversible damages in several organs such as Diabetic Nephropathy (DN) [1]. Autophagy is involved in catabolic processes and plays a key role in the degradation of damaged intracellular proteins in order to maintain intracellular homeostasis and cell integrity. Studies showed that autophagy-related protein 5 (ATG5) and Light chain 3-II (LC3-II) play a critical role in a variety of disease processes, like DN [3]. Empagliflozin (EMPA)
Figure 1: Physiology. A. Weight, B. water intake, C. urine, D. Urine protein, E. Urine creatinine, F. Urine glucose. Con group (black columns), DM mice (red columns), DM+EMPA (blue columns). * P<0.05 vs. Con, ** P<0.01 vs. Con, *** P<0.001 vs. Con, $ P<0.05$ vs. DM+EMPA, $$ P<0.01$ vs. DM+EMPA, $$$ P<0.001$ vs. DM+EMPA, £££ P<0.001 vs. one month, † P<0.05 vs. BL, †† P<0.01 vs. BL, ††† P<0.001 vs. BL.

Figure 2: Renal ATG5, LC3-II and fibronectin expression in Con, DM and DM+EMPA mice. A, E and I. Representative renal IHC staining of ATG5, LC3-II and fibronectin, respectively (Magnification x20). B, F and J Quantification of ATG5, LC3-II and fibronectin, respectively IHC staining. C and G. Representative Western blots of ATG5 and LC3-II protein levels in renal lysates. is sodium glucose transporter inhibitor (SGLT2i) which represents a new class of glucose lowering drugs and is recommended in T2DM [4]. We hypothesized that EMPA effects renal integrity and function via the autophagy mechanism. The proposed research aim to investigate the molecular effect of SGLT2i on the expression of ATG5 and its downstream collaborator LC3-II in diabetic mice model [5].

Methods: 8-week-old male mice: C57BL/6 Wild Type (Con), BTBR ob/ob (DM) and BTBR ob/ob treated with EMPA (1mg/kg/day P.O.) (DM+EMPA) were followed for 12 consecutive weeks for their weight, blood glucose and subsequent DN. EMPA preserves ATG5/LC3-II expression with SGLT2i treatment. Studies to address DM and vascular complications by selective modulation of autophagy may be translated into clinical practice approach and may lead to further studies to address DM and vascular complications by selective modulation of ATG5/LC3-II expression with SGLT2i treatment.

Results: Blood glucose level in DM mice was higher than Con, and lower in DM+EMPA. DM+EMPA mice drunk, urinated more and exerted more glucose than DM mice, yet had less protein in their urine. WB and IHC analyses revealed that renal ATG5 and LC3-II levels were reduced in DM mice compared with Con and DM+EMPA mice. Fibronectin expression was increased in DM compared to Con mice, and DM+EMPA mice.

Conclusions: EMPA treatment preserved DM mice renal dysfunction. Our data suggest that there is a link between DM and ATG5/LC3-II dysregulation and subsequent DN. EMPA preserves ATG5/LC3-II in DM mice. Our findings may be translated into clinical practice approach and may lead to further studies to address DM and vascular complications by selective modulation of ATG5/LC3-II expression with SGLT2i treatment.

ACSS2-INDUCED FATTY ACID SYNTHESIS PROMOTES NLRP3 INFLAMMAMOSE AND PYROPTOSIS OF RENAL TUBULAR CELLS IN SEPSIS-INDUCED ACUTE KIDNEY INJURY
Jian Lu and Chun-Ming Jiang
Department of Nephrology, Nanjing Drum Tower Hospital, the Affiliated Hospital of Nanjing University Medical School, P.R. China

Background and Aims: Cellular fatty acid metabolism was supposed to be tightly associated with immune responses. Pyroptosis is a form of programmed cell death dependent on the NLRP3 inflammasome activation. Previous studies have revealed that acyl-CoA synthetase 2 (ACSS2) promoted fatty acid synthesis under metabolic stress. However, whether ACSS2-mediated fatty acid metabolism can regulate pyroptosis and inflammatory responses of renal tubular cells in AKI remain unclear.

Method: lipopolysaccharide (LPS) was intraperitoneally injected to establish the sepsis mouse model, and in vitro HK-2 cell culture model was achieved by LPS stimulation. HE and PAS staining were carried out to evaluate pathological injury of kidneys in mice. The renal tissue immunostaining was conducted to detect IL-1β expression and macrophage distribution in kidney tissues of mice. Gene expression of inflammatory factors was evaluated by real-time PCR. Western Blot was conducted to the activation of the NLRP3 pathway and pyroptosis in vivo and in vitro.

Results: Here, we demonstrated that the expression of ACSS2 was significantly increased in the renal epithelial cells of mice with Lipopolysaccharide (LPS)-induced AKI when compared to wild-type mice. ACSS2 regulates NLRP3-mediated caspase-1 activation and IL-1β production through the stimulation of fatty acid synthase (FASN) in renal epithelial cells. The deletion of ACSS2 attenuated renal tubular pathological injury and inflammatory cell infiltration in an LPS-induced mouse model. Consistently, ACSS2-deficient mice displayed impaired FASN-mediated lipid synthesis and decreased IL-1β production in response to the LPS challenge. In HK-2 cells, ACSS2 deficiency suppressed NLRP3-mediated caspase-1 activation and decreased fatty acid synthesis through the downregulation of FASN. The treatment with the chemical inhibitor C75 suppressed NLRP3-mediated caspase-1 activation and pyroptosis of HK-2 cells under LPS treatment in renal tubular cells.

Conclusion: Our results suggested that ACSS2 regulated the NLRP3 inflammasome activation and pyroptosis by inducing the FASN-mediated fatty acid synthesis pathway in renal epithelial cells. These results identified ACSS2 as a potential therapeutic target in AKI.

RENALE BERIC GYCOLYSIS AND LOCAL LACTATE PRODUCTION IN AKI
Jiaying Li, Xiaoxiao Shi, Zhixin Chen, Jiatong Xu and Limeng Chen
Dongcheng-qu, P.R. China

Background and Aims: Kidney is a high energy-consuming organ depending on fatty acid β-oxidation (FAO) to fulfill energy supply. During various biological stresses in AKI, FAO shuts down, and the aerobic glycolysis is enhanced. In this study, we aimed to investigate the effect of aerobic glycolysis and local lactate production in AKI.

Methods & Results: A maleic acid (MA) induced AKI model (MA-AKI) was established by MA intraperitoneally (i.p.) in C57BL/6 mice and sacrificed after 24h. The renal function in MA-AKI mice was damaged, accompanied by proximal tubular injury and mitochondrial dysfunction. RNA sequencing revealed a relative increase in glycolytic enzymes (HK1, PKM and PFKP) mRNA levels in the AKI phase. The protein level of glycolysis-related enzymes was also elevated with increased urinary lactate significantly (0.25±0.10 versus 8.60±0.74 mmol/L, P<0.0001) in MA-AKI. Furthermore, glycolysis inhibitor 2-DG was administrated after 2h of MA injection, which improved the renal function (indicated by decreased serum creatinine (Scr), 33.52±2.78 versus 57.15±4.81 μmol/L, P<0.001), proximal tubular histopathological injuries and mitochondrial dysfunction in MA-AKI. Mechanistically, we observed a significant positive correlation between the Scr and urinary lactate levels (R² = 0.78, P < 0.0001). In order to examine the role of lactate in AKI, the mice were pretreated with oxamate, an inhibitor of lactate dehydrogenase A (LDHA), and the level of Scr (59.18±5.83 versus 28.82±3.41 μmol/L, P<0.0001) was mitigated, with the reduction of urinary lactate (8.60±0.74 versus 4.90±0.98 mmol/L, P<0.01).

Conclusion: Our study demonstrated that inhibition of aerobic glycolysis to protect kidney function in MA-AKI might be via reducing lactate accumulation.

PROTECTIVE EFFECTS OF VITAMIN D ON HYPERANDROGENEMIA-INDUCED-ACUTE KIDNEY INJURY THROUGH THE INTERACTION WITH THE RAS/INOS PATHWAY
Fatemeh Masjedi, Zeinab Karimi and Jamshid Roozbeh
Shiraz, Shiraz Nephro-Urology Research Center, Shiraz University of Medical Sciences, Shiraz, Iran

Background and Aims: The onset and development of metabolic abnormalities are closely related to polycystic ovary syndrome (PCOS). It has not yet been determined whether PCOS contributes to kidney injury, and the mechanism underlying the condition is not fully understood. Treatment with vitamin D has been shown to have beneficial effects on women with PCOS and renal disease. This study investigated the hypothesis that vitamin D supplementation exerts renoprotective effects via regulating the renin-angiotensin system (RAS)/inducible nitric oxide synthase (iNOS) pathway.

Method: Female Sprague-Dawley rats were randomly divided into five groups (n = 10): (a) control, (b) sham, (c) dehydroepiandrosterone (DHEA, 6 mg/100 g day-1 S.Q), (d) DHEA + vitamin D (1000 IU/Kg; 3 days/week), and (e) vitamin D. Plasma, ovary, and kidney levels of angiotensin-converting enzyme (ACE) activity was determined using FAPGG-based colorimetric method. The amount of NO was measured by determining the concentrations of nitrite and nitrate end products in the plasma and tissue samples using the Griess method. Histopathological changes in the ovary and kidney were also evaluated.

Results: Plasma testosterone increased in DHEA-treated rats compared with controls, indicating a hyperandrogenic state. Further, hyperandrogenemia-induced-acute kidney injury increased the plasma, renal, and ovarian angiotensin-converting enzyme (ACE) activities in association with elevations in the plasma and urine nitrate and nitrite levels; these changes were reversed by vitamin D treatment.

Conclusion: Hyperandrogenemia causes systemic abnormalities through RAS imbalance and NO metabolism disturbances, followed by apparent destruction of renal and ovarian tissues. Vitamin D supplementation attenuated these
hyperandrogenemia-associated acute kidney injuries, likely via interaction with the RAS/iNOS pathway.

COMBINED EFFECT OF DEHYDRATION, HYPERTENSION, AND AGE ON RENAL FRAILTY

Noelia Diaz-Morales¹, Rebeca Sidhu-Muñoz¹, Eva Maria Baranda Alonso¹, Annette Düwel¹, Isabel Fuentes-Calvo², Sandra M. Sancho Martínez², Carlos Martínez Salgado² and Francisco J. Lopez-Hernandez²

¹Institute of Biomedical Research of Salamanca, Salamanca, Spain and ²University of Salamanca, Salamanca, Spain

Background and Aims: Renal frailty (RF) is a premorbid and, at least partly, modifiable condition arising from diminished renal functional reserve and defective adaptive response capacity predisposing to acute kidney injury (AKI). RF ensues from subclinical wear or distortion of the renal haemodynamic and tubular homeostatic responses that defend the renal excretory function from supervening circumstances (i.e., stressors such as drugs). In this work, we aimed to study the impact of RF generated by the combined effect of the hydration state, hypertension and ageing on the nephrotoxicity developed by a low dose of cisplatin in the rat.

Method: Young Wistar rats, young spontaneously hypertensive rats (SHR), and aged Wistar rats were used. Rats in each group were randomly subject to four experimental conditions:
- Control: rats with ad libitum water intake, receiving vehicle (0.9% NaCl, i.p).
- Cisplatin: rats with ad libitum water intake, treated with 2.5 mg/kg, i.p. cisplatin.
- Water deprivation: rats deprived of water for 48 h, receiving vehicle (0.9% NaCl, i.p.).
- Water deprivation + cisplatin: rats deprived of water for the 48 h prior to 2.5 mg/kg i.p. cisplatin administration.

Tail vein blood and 24-hour urine samples were collected at basal time (B), after water deprivation (D0), and 4 days after cisplatin/vehicle administration (D4, day of maximum kidney damage). Haematocrit was measured and plasma osmolality, plasma creatinine (Jaffé reaction) and urea (Jung method) concentrations were determined. Urine samples were analysed for volume (urinary flow), osmolality, and proteinuria (Bradford method). Body fluid composition was measured by bioimpedance spectroscopy with an ImpediVETTM VetBIS1 device.

Results: All rats showed clear signs of dehydration after 48 hours of water deprivation: weight loss, increases in plasma osmolality and haematocrit (more pronouncedly in young Wistar and SHR than in aged animals), and reduced flow of a highly concentrated urine (i.e., with elevated osmolality). Bioimpedance analysis revealed a parallel loss of intracellular and extracellular water and net loss of total body water (explaining most of weight loss), with no changes in the liquid distribution between the intracellular and extracellular compartments. Dehydration was reverted after 4 days of rehydration in vehicle-treated rats, and no alteration of renal function was observed due to water deprivation. Administration of cisplatin in young, normohydrated Wistar rats showed minimal loss of renal function that was not worsened by water deprivation. Hypertensive rats showed completely normal renal function when cisplatin was administered under normohydration. Interestingly, however, dehydrated SHR did suffer a cisplatin-induced AKI (significant increases in plasma creatinine, plasma urea and proteinuria). In aged Wistar rats, cisplatin compromised renal function (as supported by increases in plasma creatinine and urea concentration), and this effect was significantly amplified by water deprivation.

Conclusion: This study suggests that dehydration in fully competent young rats is not in itself a significant risk factor for AKI, while the combination of dehydration and hypertension in young rats significantly increases the risk of AKI. Furthermore, ageing poses animals in a state of frailty that renders their kidneys unable to respond to stressors (such as a low dose of cisplatin). Frailty is boldly worsened in dehydrated aged animals. In perspective, models reproducing conditions of increased vulnerability to AKI provide useful tools to search for biomarkers pre-emptively predicting undesired health outcomes before exposure to stressors, and for developing preventing strategies.

Abstracts
ATP6V0A4 GENE MUTATION-ASSOCIATED NEPHROPATHY
Siqi Peng1, Bin Wang2 and Xiao Liang Zhang2
1Southeast University, Nanjing, P.R. China and 2Zhong Da Hospital, Southeast University School of Medicine, Nanjing 210009, Jiangsu Nephrology, China. Nephrology, Nanjing, P.R. China

Background and Aims: The ATP6V0A4 gene is localized to chromosome 7q33-34 and encodes for vacuolar H+-ATPase (V-ATPase) α4 subunit. Decreased V-ATPase function due to mutations in the ATP6V0A4 genes could cause H+ excretion defect of α-intercalated cells in the renal collecting duct, resulting in hereditary distal renal tubular acidosis (dRTA). However, crucially, no gain-of-function mutations in the ATP6V0A4 gene have been reported previously. This study reports a gain-of-function mutation of ATP6V0A4 gene occurred in a 32-year-old male with metabolic alkalosis, hypokalemia and hearing loss, and further explore potential pathogenic mechanisms of this mutation.

Method: Clinical information was collected from the proband and his family members. Kidney tissue samples were collected for morphological observation and immunohistochemical staining. High-throughput sequencing analyses were done for the proband and his parents. ATP6V0A4 wild-type and mutant plasmids were constructed and used to transfect the 293T cells. After 48 hours of transfection, the expression of ATP6V0A4 was verified using WB analyses and V-ATPase activity was measured by ultraviolet spectrophotometry.

Results: The proband and his father both suffered from severe hypertension and hearing loss. Blood tests showed hypokalemia, metabolic alkalosis and renal insufficiency. Urinalysis indicated acidic urine. Laboratory tests on admission are shown in Table 1. Renal biopsy suggested malignant hypertensive kidney injury. Whole-exome sequencing demonstrated that the proband carried the heterozygous mutation c.1534G>T; p.V512L in exon 15 of the ATP6V0A4 gene. Sanger sequencing confirmed that the variant was inherited from his father. The immunohistochemical results implied the expression of V-ATPase α4 was significantly higher in renal tissues from proband than that of the control who was diagnosed with minimal change disease (Figure 1B). WB analysis showed 293T cells transfected with ATP6V0A4 mutant plasmids with darker protein bands, suggesting higher expression of V-ATPase α4 (Figure 1D). The cells transfected with mutant ATP6V0A4 plasmids showed significantly higher V-ATPase activity compared with wild-type ATP6V0A4 plasmids transfected cells (Figure 1E).

Conclusion: The ATP6V0A4 c.1534G>T; p.V512L mutation is a gain-of-function mutation and this result indicates the possibility that this mutation might enhance the normal physiological function of the V-ATPase, and likely contributes to the increased hydrogen ions excretion and thereby to the development of metabolic alkalosis (Figure 1F).

Method: Renal ischemia-reperfusion injury (IRI) in mice as a model of acute kidney injury (AKI) were set as a platform to investigate the role of LMO7 and its functional interacting proteins in the pathological progression of compromised tubular epithelial integrity. Additionally, renal epithelial cells cultured in hypoxia as the pathogenic condition equivalent to AKI were also employed to investigate the role of LMO7. We also search the STRING database with LMO7 as query to find out its functional interacting proteins. Pathological pattern associated with LMO7 and its functional interacting protein in mice suffering from AKI as well as loss of tubular epithelial integrity were examined by immunofluorescent visualization. The LMO7 in urine as well as conditioned medium determined from medium of hypoxia culture were quantified by Western blot analysis.

Results: Renal damage in IRI mice showed loss of epithelial integrity by histochemical staining, presence of LMO7 in urine, and high serum creatinine on the third day post IRI. Under the periodic acid-schiff (PAS) staining, loss of epithelial integrity is visible in proximal tubules, Henle's loops, and collecting ducts at the third day after reperfusion, and brush border impairment is observed in the outer stripe of the outer medulla. Most severe damages in renal tubules are present in Henle's loops where the epithelia express abundant LMO7. In the AKI mice, the LMO7 in renal tubules was apparently lower in Henle's loops. Additionally, the VANGL1, a LMO7 interacting protein participated in epithelial integrity and planar cell polarity in kidney, is also absent in Henle's loop of AKI mice. Hypoxia and glucose deprivation in cultured renal epithelial cells resulted in loss of epithelial integrity, and downregulation of LMO7 and VANGL1. LMO7 was also identified in conditioned medium in which cells exposed to hypoxia but not normoxia. Additionally, the LMO7 was detected in urine of some patients with chronic kidney disease. Conclusion: Presence of LMO7 in urine has been promising in experimental models holding compromised epithelial integrity. These approaches identified the role of LMO7 in maintaining epithelial integrity and that LMO7 being released into urine after renal epithelial damage as a novel marker for loss of REB.

CALYCOSIN ATTENUATES RENAL ISCHEMIA/REPERFUSION INJURY BY SUPPRESSING INFLAMMATION VIA PPARγ/EGR1 PATHWAY

Ningxin Zhang and Yan Xu

Nephrology, Qingdao, P.R. China

Background and Aims: Renal ischemia reperfusion injury (IRI) is a leading cause of AKI, and delayed recovery of IRI contributes to chronic kidney disease and even end-stage kidney disease. However, there is no effective prevention and treatment for IRI-AKI. Calycosin (CAL), an isoflavonoid phytoestrogen isolated from Radix astragali, has various pharmacological activities. However, whether CAL has a protective effect on renal IRI and its mechanism remains elusive. In this study, we aim to explore the effect and mechanism of CAL on IRI-AKI through bioinformatics and experiments in vitro and in vivo models, so as to provide potential candidate drugs for early intervention treatment of IRI-AKI.

Method: (1) In the first part, mice were intragastrically given CAL daily for 7 d, and subjected to bilateral renal artery occlusion for 35 min followed by reperfusion 24 h to establish the renal IRI model. HE staining was used to evaluate the renal pathological injury, and the renal function including serum creatinine (SCR) and blood urea nitrogen (BUN), was also examined. Meanwhile, inflammatory factors were detected. In cell experiments, HK-2 cells pretreated with 8.16 and 32 μM CAL were subjected with hypoxia/reoxygenation (H/R), and the effect of CAL on H/R induced cell injury were investigated by qRT-PCR and ELISA. (2) In the second part, the differentially expressed gene (DEGs) of IRI-AKI were obtained by bioinformatics analysis of GSE52004 dataset. Subsequently, the hub gene with the highest score was obtained by protein-protein interaction (PPI) analysis, and its upstream transcription factors were predicted by JASPAR database. In IRI-AKI mice, the predicted results of bioinformatics were verified by qRT-PCR, Western Blot and immunohistochemistry. In HK-2 cells, the regulatory relationship between the hub gene and its upstream transcription factor and the role of them in inflammatory process were verified by double luciferase reporter gene and siRNA. Furthermore, molecular docking was used to predict the interaction between CAL and the transcription factor, and the role of the target protein in the protection of H/R HK-2 cells by calycosin was verified by siRNA.

Results: (1) In the mice with renal IRI, CAL dose dependently alleviated SCR and BUN levels and renal tubular injury score. Meanwhile, the mRNA level of inflammatory cytokines were markedly inhibited by CAL pretreatment. (2) In the pre-experiment in vitro, the toxicity of CAL was negligible at concentrations of 32 μM or less for 24 h incubation. In H/R induced HK-2 cells, CAL incubation reduced the levels of hypoxia-inducible factor (HIF) and the inflammatory cytokines. (3) 58 DEGs were identified in the kidney of IRI mice. PPI analysis showed early growth response 1 (EGR1) is the hub gene the highest score. JASPAR database predicted that peroxisome proliferator-activated receptor γ (PPARγ) is the upstream transcription factor of EGR1. (4) In kidney after IRI, EGR1 was up-regulated and PPARγ was down-regulated, while the pretreatment of CAL decreased EGR1 and increased PPARγ in a dose-dependent manner. (5) In H/R induced HK-2 cells, after inhibited the expression of EGR1 by siRNA, the level of inflammatory factors decreased significantly, suggesting that EGR1 participated in and promoted the inflammatory process of tubular cells. In addition, dual luciferase reporter gene assay confirmed that PPARγ interact with EGR1 promoter, as EGR1 increased after EGR1 promoter plasmid transfection but decreased after PPARγ overexpression. (6) In mice after renal IRI, CAL promote PPARγ expression markedly. According to molecular docking, CAL, as a ligand, could be embedded into the orthosteric pocket of PPARγ with a binding energy of -6.46 kcal/mol. In CAL incubated cells, PPARγ increased and EGR1 decreased considerably. However, the protective effect of CAL on H/R induced inflammation was absent when PPARγ knockdown, indicated that CAL ameliorate renal IRI and inhibit inflammation via PPARγ/EGR1.

Conclusion: CAL could significantly modulate inflammation by targeting the PPARγ/EGR1 pathway, contributing to the alleviation of renal IRI.
RESOLVIN D1 ATTENUATES SEPSIS INDUCED ACUTE KIDNEY INJURY TARGETING MITOCHONDRIA AND NF-κB SIGNALING PATHWAY
Liya Wang, Jiameng Li and Baihai Su
P.R. China

Background and Aims: Acute kidney injury is a highly common and multifactorial renal disease resulting in significant morbidity and mortality, especially sepsis-induced acute kidney injury. There is no effective therapy available to treat or prevent sepsis-induced acute kidney injury. One of the specialized pro-resolving mediators, Resolvin D1 exhibits special anti-inflammatory effects in several inflammatory disease models, but there is little evidence about the effect and mechanism of Resolvin D1 in sepsis-induced acute kidney injury. To explore the renal protective role of RvD1 in SI-AKI and to further explore the inherent pathophysiological mechanism, especially the role of mitochondrial function and NF-κB signaling pathway, invitro and invivo experiments were conducted.

Method: We conducted experiments to explore the effect and mechanism of Resolvin D1 in sepsis-induced acute kidney injury. In vitro, human proximal tubular epithelial cells were used to test the apoptosis ratio, cell viability and reactive oxygen species level. In vivo, C57BL/6 mice were injected with lipopolysaccharide to establish a sepsis-induced acute kidney injury model. Renal function and structure, apoptosis ratio of kidney cells, mitochondrial structure and function and related protein and gene levels were assessed.

Results: In vitro, the resolvin D1-treated group showed higher cell viability and lower reactive oxygen species levels and apoptosis ratios than the LPS group. In vivo, Resolvin D1 can not only improve renal function and mitochondrial function but also reduce the apoptosis ratio, while mediating mitochondrial dynamics and inhibiting NF-κB pathway.

Conclusion: Resolvin D1 has a good renoprotective effect by maintaining mitochondrial dynamics and inhibiting the NF-κB pathway. This provides an important basis for us to further develop the clinical therapeutic value of RvD1 in acute renal injury in sepsis.

LINACLOTIDE IS PROTECTIVE AGAINST RENAL ISCHEMIA-REPERFUSION INJURY
Yukihiro Hitaka, Kimihiko Nakamura, Naohito Isoyama and Koji Shiraiishi
Yamaguchi University Hospital, Ube, Japan

Background and Aims: Renal ischemia-reperfusion injury is associated with delayed graft function and poor long-term graft survival following transplantation. Linaclotide is a guanylate cyclase C (GC-C) receptor agonist that increases intracellular cGMP concentrations and promotes intestinal transport capacity by activating the GC-C receptor. Since CKD is a deficiency of cGMP in the kidney, increasing cGMP in the kidney by linaclotide would suppress fibrosis, protecting the kidney.

Method: An AKI rat model of unilateral nephrectomy plus contralateral ischaemia (30 min) and impaired reperfusion (up to 14 days) was used. Linaclotide was administered before and after surgery for 2 weeks, and blood and renal tissue samples were collected to determine its effect on renal function and whether it was protective against the progression of CKD.

Results: In the I/R injury+ group, creatinine levels were lower in the linaclotide-treated group than in the non-treated group. Sirius red staining showed significant improvement in fibrosis. The hydroxyproline content of kidneys was determined by the basic hydroxyproline method. RNA seq showed that genes down-regulated in I/R injury+ were the oxidative stress markers SOD3 and Gpx1. The expression of genes down-regulated in I/R injury+ was up-regulated to a degree similar to that in I/R injury- by treatment with linaclotide. These data suggest that linaclotide may ameliorate renal fibrosis by suppressing renal dysfunction through its antioxidant effects.

Conclusion: The antioxidant effect of linaclotide was found to suppress the decrease in renal function caused by I/R. We would like to apply this finding to human renal transplantation in the future to prevent renal function deterioration due to I/R.

STING CONTRIBUTES TO LPS-INDUCED TUBULAR INFLAMMATION BY ACTIVATING IRE1/XBP1 PATHWAY IN ACUTE KIDNEY INJURY

Yun Cao

Hainan General Hospital (Hainan Affiliated Hospital of Hainan Medical University), Department of Nephrology, P.R. China

Background and Aims: Innate immunity and inflammation were recognized as the key factors for the progression of acute kidney injury (AKI) induced by lipopolysaccharide (LPS). Stimulator of interferon genes (STING) has emerged as a critical component of innate immune and inflammatory responses. This study aimed to explore the role of STING in LPS-induced tubular inflammation in AKI.

Method: 1. The AKI mice models were induced by intraperitoneal injection of LPS. Mice were randomly divided into CTL group, LPS 24 g group and LPS 48 g group: (1) STING protein expression in tubules was detected by IHC staining; (2) STING protein expression in kidney cortices was detected by WB.
2. The tubule-specific STING knockout (STING-cKO) mice were generated. Then WT mice and STING-cKO mice were randomly divided into WT group, WT+LPS group, STING-cKO group and STING-cKO+LPS group: (1) Blood samples and urine samples were collected for Scr, BUN and ACR measurement; (2) Tubular pathological changes were detected by PAS staining; (3) Inflammatory cell infiltration in kidney cortices was detected by IHC and IF staining; (4) Pro-inflammatory cytokines’ mRNA level in kidney cortices was detected by qPCR.

Results: 1. STING was activated in tubules from LPS-induced AKI mice. (2) STING protein expression in kidney cortices was detected by WB.
2. STING-cKO significantly suppressed LPS-induced renal dysfunction, tubular pathological changes, tubular inflammation and IRE1/XBP1 pathway activation.
3. The tubule-specific STING knockout (STING-cKO) mice were generated.

Conclusion: STING contributes to LPS-induced tubular inflammation by activating IRE1/XBP1 pathway. Targeting STING may be a promising therapeutic strategy for preventing septic AKI.

THE INTEREST OF THE COMBINATION OF AN ANTIOXIDANT AND ANGIOTENSIN II RECEPTOR ANTAGONISTS IN THE REDUCTION OF RENAL FIBROSIS

Leila Azouaou1,2

1Research Laboratory of Oxidative Stress, Kidney and Associated Complications, University Algiers 1, Faculty of Medicine, Algeria and 2Service of Nephrology, CHU of Parnet, Faculty of Medicine, University of Algiers 1 Algeria, Algiers, Algeria

Background and Aims: Chronic kidney disease represents one of the frequent pathologies of non-communicable diseases where the mortality rate is high. Oxidative stress is one of the main causes of the deterioration of renal function. The aim of this work is to develop a new therapeutic molecule with an anti-fibrotic effect associated with an antioxidant to increase renal clearance.

Method: This is an experimental study using the aminonucleoside model of puromycin (PAN) on Sprague-Dawley rats weighing between 100 and 150 g. Mice are resistant to the effect of PAN Administration of PAN can be subcutaneous (SC) intravenous (IV) and intraperitoneal (IP). The dosage for IV and IP administration of PAN is generally 150 mg/kg body weight and 120 mg/kg body weight for SC administration. Control rats receive an isotonic saline solution. The progression of glomerular lesions to glomerular fibrosis depends on the cumulative dose of PAN. The single injection of PAN induces reversible fibrosis lesions between the seventh and one month and after re-injection irreversible lesions. The mice benefited from PAN 2 injections on the 1st day and on the 40th day, the new molecular association was made on 15 days and 50 days.

Results: Two to four days after the injection of PAN, a disorganization of the ultrastructure of the pedicles is observed with a flattening of the podocyte feet, an effacement of the pedicles, a modification of the actin cytoskeleton and the disappearance of the diaphragm of cleft. The ultrastructural changes observed 10 days after PAN injection lead to podocyte detachment contemporary with proteinuria. If the aggression continues, podocyte apoptosis is associated with histological appearance of segmental and focal hyalnosis. After the injection of the molecular combination, a regression of the lesions was observed 15 days after the first injection and 30 days after the second injection.

Discussion: The anti-fibrotic-antioxidant drug combination has a significant anti-fibrotic effect, especially during the first injection, the effect is less important during the evolution of histological fibrosis. The antioxidant gave a synergistic effect to the anti-fibrotic effect.

Conclusion: The experimental study is very promising concerning the antioxidant ARII molecular association while waiting for the clinical trial that will hopefully be promising for this new association.

HIF-1α REGULATED LncRNA-ATP6V0E2-AS1 MEDIATES HYPOXIA-INDUCED MITOPHAGY IN RENAL TUBULAR CELLS

Chi-Yuan LI

Graduate Institute of Biomedical Sciences, China Medical University, Department of Anesthesiology, China Medical University Hospital, Taichung, Taiwan, Rep. of China

Background and Aims: Mitophagy activation is crucial for hypoxia signaling in acute kidney injury (AKI). Selective removal of damaged mitochondria is mediated through a concerted function of coding and non-coding RNA expression. Insights on HIF-1α signaling in lncRNA-regulated mitophagy mechanism are not known. The study aims to investigate the role of hypoxia-inducible factor 1α (HIF-1α) regulated long non-coding RNA (lncRNA) ATP6V0E2-AS1 in acute kidney injury (AKI) by examining its effect on mitophagy.

Method: Mitophagy proteins (PINK1, p-PARKIN, LC3) were determined through western blot analysis. Immunofluorescence studies of PINK1 mitochondrial translocation and LC3/TOMM20 localization were determined using confocal analysis. HIF-1α interaction with lncRNA-ATP6V0E2-AS1 was analyzed by dual-luciferase reporter assay.

Results: Hyoxia upregulated PINK1, p-PARKIN, LC3 expressions, and mitophagosome in HK-2 cells. Overexpression and knockdown studies of hypoxia-regulated lncRNA-ATP6V0E2-AS1 significantly regulated PINK1/p-PARKIN expressions, subsequent PINK1 mitochondrial co-localization, and mitophagosome formation. shHIF-1α knockdown in HK-2 cells revealed that HIF-1α mediates PINK1/p-PARKIN mitophagy regulation under hypoxic conditions. In detail, HIF-1α binds to the promoter of lncRNA-ATP6V0E2-AS1 and down-regulates its expression under hypoxia. Deficiency of both HIF-1α and lncRNA-ATP6V0E2-AS1 reversed shHIF-1α mediated suppression of PINK1 expression and mitophagosome formation. Further, ATP6V0E2-AS1 post-transcriptionally regulates PINK1 expression by RNA-RNA interaction.

Conclusion: Altogether, our study shows novel findings on the HIF-1α mediated lncRNA-ATP6V0E2-AS1 in hypoxia-induced mitophagy regulation in the renal tubular cells. Thus, downregulated ATP6V0E2-AS1 expression with subsequent mitophagy activation is critical for hypoxia-induced mitophagy regulation through HIF-1α/ATP6V0E2-AS1/PINK1 axis.

PRO-INFLAMMATORY EFFECTS OF BISPHENOL A AND POLYETHYLENE MICROPLASTICS ON HUMAN RENAL TUBULAR CELLS

Alice Beltrame1, Noemi Rumeo2, Edoardo La Porta3, Daniela Verzola1, Andrea Angeletti3, Francesca Lugani3, Micaela Gentile4, Paolo Cravedi4, Cristina Artini5, Stefano Alberti6, Claudia Caboni3, Marika Bertoli1, Silvio Chiarenza3, Enrico Eugenio Verrina3, Gian Marco Ghiggeri3, Pasquale Esposito6 and Francesca Viazzi6

1University of Genova, Department of Internal Medicine, Genova, Italy, 2Laboratory of Molecular Nephrology, Scientific Institute for Research and Health Care, IRCCS Istituto Giannina Gaslini, Genova, Italy, 3Nephrology Dialysis and Transplantation, IRCCS Istituto Giannina Gaslini, Genova, Italy, 4Icahn School of Medicine at Mount Sinai, Department of Medicine, Translational Transplant Research Center, New York, United States of America, 5Department of Chemistry and Industrial Chemistry, DCCI, University of Genoa, Genova, Italy and 6University of Genova, Department of Internal Medicine, IRCCS Ospedale Policlinico San Martino, Genova, Italy

Background: Growing evidence shows that microplastics (MP) and their chemical derivates contaminate the environment and accumulate in the gut, liver, lungs, and kidneys. Furthermore, MP can adsorb a wide range of toxic substances (heavy metals, polycyclic aromatic hydrocarbons, Bisphenol A [B]), causing the accumulation of multiple pollutants and so, enhancing their toxicity (the so-called “Trojan Horse” effect). An epidemic of chronic kidney disease (CKD) of uncertain etiology is emerging worldwide and understanding the involvement of environmental pollution may be critical for health policies and public health responses. Inflammation is intimately linked to renal disease, and proinflammatory cytokines and chemokines are important mediators of fibrosis in the tubulointerstitial compartments.

Aims: To evaluate the effects of B and Polyethylene (Pe)-MPs and their combination B+Pe-MP on human renal tubular cells (HK-2). To this end, the activation of the Aryl hydrocarbon Receptor (AHR), a transcription factor binding xenobiotics, and the expression of inflammatory molecules were explored.

Method: HK-2 were exposed to 0 (No Treated cells: NT), 100 nM B, 0.2 mg/ml Pe-MP (diameter 1-4 μm), and B+Pe-MP for 5-24 hrs. Cell uptake of (FL)uorescent Pe-MP was visualized by microscope; viability was assessed by
MTR; AHR, HSP90, CCL2, CCR2, CCL5, and CCR5 expression was studied by rt-PCR. Western blot, and immunofluorescence.

**Results:** After 5 hrs exposure, a FLPe-MP cytoplasmatic and perinuclear deposition was observed (Figure 1). After 24 hrs, Pe-MP and B+Pe-MP exposure reduced cell viability (~20% vs NT p < 0.001). The treatments increased AHR expression (1.5-3-fold vs NT, p < 0.05-0.001), which had a nuclear localization both at 5 and 24 hrs. Conversely, HSP90 expression, a chaperone that keeps AHR inactive, decreased (~20-40% vs NT, p < 0.05) (Figure 2). After 2 hrs, CCL2 levels rose (1.8-3.5 fold, p<0.05-0.001) vs NT) as well as its receptor CCR2 (2.3-6.7 fold, p<0.05-0.01). Similarly, CCL5 and CCR5 were, respectively, 1.6-2.7 and 3.8-4.8 fold overexpressed with respect to NT (p < 0.05-0.01). Interestingly, the co-exposure significantly enhanced the expression of these inflammatory molecules.

**Conclusion:** Our data suggest that B and Pe-MPs induce a pro-inflammatory response in renal tubular cells and that the combined effect of B and Pe-MPs induces a worse effect on HK2 than B or MPs alone, supporting the theory of the "trojan horse" effect mediated by MPs. Therefore, MPs could be a trigger of kidney damage, thus confirming the potential impact of the environment on the pathogenesis of the renal disease. Moreover, these data could address the importance of investigating any health implications associated with MPs.

**FATTY ACID BINDING PROTEINS (FABPS) INHIBITION IMPAIRS METABOLIC HOMEOSTASIS IN RENAL TUBULAR CELLS**

**Jorge García-Giménez, Gina Marcela Córdoba David, Alberto Ortiz and Adrián Mario Ramos Cortassa**

Instituto de Investigación Sanitaria-Fundación Jiménez Díaz (IIS-FJD), Nephrology and Hypertension Laboratory, Spain

**Background and Aims:** The fatty acid binding proteins family of lipid chaperones (FABPs) mediate lipid trafficking and lipid-mediated metabolic pathways. Despite inhibition of induced FABPs may be beneficial in kidney disease, their enrolment in renal metabolic homeostasis remains elusive. Therefore, we approached this issue in cultured renal tubular cells.

**Method:** FABP mRNA and protein expression were evaluated in C57/BLE mice subjected to folic-acid kidney injury. Mitochondrial redox status, proliferation, death rate, and fatty acid oxidation (FAO) were studied in renal tubular cells in conditions of overall FABP inhibition with BMS309403. In these conditions, lipid trafficking was addressed by oil red content and pulse-chase assays using the fluorescent lipid RedC12. Delivery of RedC12 within LD or mitochondria was followed with BODIPY493/503 and Mitotracker and assays using the fluorescent lipid RedC12. Delivery of RedC12 within LD or mitochondria was followed with BODIPY493/503 and Mitotracker and confocal microscopy. Free and esterified RedC12 species were assessed by thin-layer chromatography (TLC). The impact of ATGL lipase activity on cellular behaviour and bioenergetics were assessed by diethylumbelliferyl phosphate (DEUP)-mediated inhibition.

**Results:** Kidneys from mice with AKI exhibited early lowered FABPs tubular expression. In serum-depleted murine tubular cells, pharmaceutical FABPs inhibition with BM309403 (BMS) led to sudden necrosis, whereas, in non-depleted cells, BMS eventually leads to apoptosis, increased the mRNA expression of proinflammatory cytokines and oxidative stress-responsive genes, and response in proliferation. BMS also rapidly decreased ATP levels consistent with FAO inhibition and induced adaptive AMPK phosphorylation/activation and FAO gene program (but not glycolytic gene expression). BMS also mediates mitochondrial depolarization, mitochondrial oxidative stress and decrease of mitochondria number. Serum-depleted cells revealed lipid droplet (LD) voiding and RedC12 delivery to mitochondria. By contrast, in BMS-treated cells growing in serum, despite the lowered ATP content and transcriptional FAO upregulation, RedC12 neither localized with LDs nor with mitochondria, suggesting a low-energy state by impairment of both lipid transit and FAO. Accordingly, TLC assessment did not show lipid breakdown-derived products, which otherwise did appear in serum-depleted cells doing FAO. Mechanistically, ATGL inhibition protects from general ROS production, LD voiding and apoptosis.

**Conclusion:** In brief, FABP inhibition disrupts tubular energetical status and favours cell stress. Thus, protecting FABP activity could help to preserve tubular metabolic homeostasis during early kidney damage.

China

**Background and Aims:** COVID-19, caused by severe acute respiratory syndrome coronavirus (SARS-CoV-2), is a progressive viral pneumonia with a broad spectrum of clinical manifestations involving multiple organs. Acute kidney injury (AKI) is common in COVID-19, especially in critically ill patients. Our previous study proved that kidney-specifically overexpressing SARS-CoV-2 N protein induces AKI, which become worsen in mice under ischemic condition. Clinically, CRP is a risk factor for AKI in COVID-19 patients. Recent clinical study showed that CRP Apheresis is able to effectively remove the plasma CRP and thus improve the clinical outcome in critically ill COVID-19 patients. We thus hypothesize that CRP may not only be a biomarker or risk factor, but also a potential mediator or novel therapeutic target for COVID-19 AKI.

**Method:** The role of CRP in COVID-19 AKI was investigated in a mouse model of AKI induced by ultrasound-microbubble-mediated kidney-specifically transferring SARS-CoV-2 N-expressing plasmids in CRP-wide-type (WT) and Transgenic (Tg) mice. We also developed a novel therapy for SARS-CoV-2 N-induced by targeting CRP signaling with a neutralizing anti-CD32 antibody both in vivo and in vitro.

**Results:** In COVID-19 patients with AKI, serum levels of CRP were significantly elevated when compared with non-AKI group. In mice, kidney-specifically overexpressing SARS-CoV-2 N protein caused AKI including tubular necrosis and elevated levels of serum creatinine and BUN in CRP WT mice which became more severe in CRP Tg mice. Importantly, targeting CRP-CD32 signaling with a neutralizing antibody to CD32 significantly inhibited SARS-CoV-2 N-protein-induced AKI in CRP Tg mice. Mechanistically, we uncovered that CRP promoted SARS-CoV-2-N protein-induced AKI via the Sma3/p21-dependent G1 cell cycle arrest and NF-kB/p65-driven renal inflammation, which was blocked by anti-CD32 antibody in vivo and in vitro.

**Conclusion:** CRP is not only a biomarker or risk factor, but also a mediator in SARS-CoV-2 N-protein-induced AKI. CRP signals through CD32 mediate SARS-CoV-2-N-induced AKI via mechanisms associated with the Sma3-p21-dependent G1 cell cycle arrest and NF-kB/p65-driven renal inflammation. Targeting CRP-CD32 signaling may represent as a novel therapy for COVID-19-associated AKI.

**HISTOLOGICAL STUDY OF KIDNEY INJURY ASSOCIATED WITH IMMUNE CHECKPOINT INHIBITORS COMBINED WITH CHEMOTHERAPY IN A MURINE MODEL**

**Javier Tascón1, Alfredo G. Casanova1, Laura Vicente-Vicente1, Moisés Pescador1, Ana Isabel Morales Martín1,2,3 and Marta Prieto1**

1Universidad de Salamanca, Salamanca, Spain, 2Institute for Biomedical Research of Salamanca (IBSAL), Salamanca, Spain and 3Translation Research on Renal and Cardiovascular Diseases (TRECARD), Salamanca, Spain

**Background and Aims:** The role of CRP in COVID-19 AKI was investigated in a murine model of AKI induced by ultrasound-microbubble-mediated kidney-specifically transferring SARS-CoV-2 N-expressing plasmids in CRP-wide-type (WT) and Transgenic (Tg) mice. We also developed a novel therapy for SARS-CoV-2 N-induced by targeting CRP signaling with a neutralizing anti-CD32 antibody both in vivo and in vitro.

**Method:** A murine model was designed in C57BL/6 mice treated with the combined therapy of cisplatin (10 mg/kg, single dose) and anti-CTLA-4 (10 or 15 mg/kg/day, for 6 days) administrated by intraperitoneal injection. In addition, groups treated with drug monotherapies and a control group were included. On the day of sacrifice (day 6) the kidneys were collected and histological sections were made and stained with hematoxylin-eosin. Histological quantification of kidney damage was performed blindly following a tissue damage quantification protocol. For this, 10 photos were taken per kidney (600X), 5 of the external cortex and 5 of the corticomedullary region. Each photo was segmented into 6 areas and a score was assigned to each area as follows: 0: no damage, 1: damage up to 1/3 of the area, 2: damage between 1/3 and 2/3, 3: damage above 2/3.
1/3 and 2/3 of the area, and 3: damage over 2/3 of the area. Subsequently, the mean scores of the kidneys from the same experimental group were calculated, as well as the standard error of the mean. Data was analyzed with the statistical software SPSS®.

Results: Our results showed tubular renal damage associated with cisplatin treatment. It was more pronounced in the external cortical area. However, no structural alterations associated with ICI treatment were found. Co-treatment with both drugs potentiated renal structural damage from cisplatin.

Conclusion: This potentiation was more evident in the corticomedullary region, so it seems that the drugs combination causes a deeper lesion in the kidney than cisplatin monotherapy. Our study suggests that the combined therapy of anti-CTLA-4 and cisplatin could induce generalized tubular lesions.

ACTIVATION OF GPR120 IMPROVES THE SENESCENCE OF TUBULAR EPITHELIAL CELLS IN SEPTIC ACUTE KIDNEY INJURY
Letian Yang, Bo Wang, Liang MA and Ping Fu
West China Hospital, Sichuan University, Division of Nephrology, Kidney Research Institute, Chengdu, PR. China

Background and Aims: Acute kidney injury (AKI) is a serious clinical complication that has high morbidity and mortality. Although there have been substantial advances in understanding AKI mechanisms, at present, there are no effective therapies to treat or prevent it.

Method: We had formerly found that TUG891, a GPR120 (a member of the G protein-coupled receptor (GPCR) family) agonist, alleviated tubular damage as well as renal dysfunction in mice with AKI. Nevertheless, the multifunctional effects of FFAR4 in the kidney have not been well described.

Results: In the current research, the GPR120 expression was abnormally reduced in tubular epithelial cells (TECs) of cecal ligation/perforation induced AKI mice, respectively. Systemic and conditional TEC-specific knockout of GPR120 aggravated renal function and pathological damage, whereas GPR120 activation by TUG-891 alleviated the severity of disease in AKI mice involved cisplatin. Notably, GPR120, as a key determinant, was firstly explored to regulate the cellular senescence in TECs and AKI mice injured kidneys, as represented through the activity of senescence associated β-galactosidase (SA-β-gal), marker protein p21, p53, Lamin B1, phospho-histone H2A.X, phospho-Rb expression, and secretory phenotype IL-6-6 level. Mechanistically, pharmacological activation and overexpression of FFAR4 reversed the decrease of aging-related SirT3 protein, where GPR120 regulated SirT3 expression to exhibit anti-senescence effect via Gq subunit-mediated CaMKKβ/AMPK signaling in cisplatin-induced mice and tubular epithelial cells.

Conclusion: These results underline the primordial role of renal tubular GPR120 in the cellular senescence through AMPK/SirT3 signaling and define GPR120 as a target for underlying drugs against septic AKI.

1Hospital del Mar Medical Research Institute (IMIM), Nephrology (GREN), Barcelona, Spain and 2IrsiCaixa – AIDS Research Institute, Virus-Host Interactions (VIHIT), Badalona, Spain

Background and Aims: In diabetic patients, hyperglycemia has been associated with a hypoxic state that contributes to an increased rate of morbidity due to Acute Kidney Failure (AKI). For this reason, we are interested in studying the molecular mechanisms involved in the development of AKI to contribute to the search for effective therapies that can help prevent these episodes. We focused on ADAM17, a disintegrin and metalloproteinase that sheds the ectodomains of cell surface proteins, among which inflammatory cytokines stand out. In an animal model, we showed that the absence of ADAM17 in the renal tubule reduces protein expression related to fibrosis and inflammation induced by diabetes. In this context, we aimed to study the role of ADAM17 in modifying the expression of inflammatory molecules regulated by interferon (IFN) in renal proximal tubule cells subjected to hyperglycemic stress. In this study, we analyzed the effect of ADAM17 deletion in human renal tubular cells (HKC-8) incubated in high-glucose medium and subjected to hypoxia.

Method: ADAM17 was depleted using CRISPR/Cas9 (ADAM17-KO). Cells were incubated for 6 h or 24 h with high (35 mM HGl) or normal (5.5 mM NG) glucose concentrations and were subjected to hypoxia plus 2h re-oxygenation (HIXP). Gene expression of several IFN-regulated inflammatory markers (IL6, IL8, CXCL10, ISG15, IL1a, IL1b, IL12A, CCL5, and CCL2) was determined in wild-type (WT) and ADAM17-KO cells.

Results: The absence of ADAM17 in HKC-8 cells induced changes in the mRNA expression of genes controlled by IFN, which is accentuated by the hyperglycemic stimulus. Under hypoxic and re-oxygenation conditions, these changes were in the same line, with more discrete values compared to control cells. TNFa, CXCL10 and LNC2 were the most relevant genes reduced in injury conditions in the ADAM17-KO cell line.

Conclusion: ADAM17 deletion modulates the expression of most IFN-regulated genes that could undergo post-transcriptional changes and subsequently act as an acute mechanism of protection from injury. The results show that ADAM17 plays a major role in the underlying inflammatory response to acute kidney injury, indicating its potential as a therapeutic target. The analysis of circulating proteins will provide information about this process to better understand the mechanism of action of ADAM17 in the protection of renal tubular damage.

PD1/PD-L1 genes in peripheral blood lymphocytes in recipients who de-novo DSA positive or negative after kidney transplantation (KTX).

Method: In this study, the expression levels of PD-1, PD-L1 genes were determined using the Real-Time Quantitative PCR method from peripheral blood samples of 22 KTX patients with de-novo DSA positive, 20 KTX patients with DSA negative and 21 healthy control (Table 1). Our patient groups were PRAnegative before transplantation. Expression (%) levels of target cells were evaluated by flow cytometry method. IBM SPSS Statistics for Windows Version 22 and R 3.3.2 software were used to evaluate the data.

Results: PD-1 expression level was higher in the KTX patients with de-novo DSA positive compared to the KTX patients with DSA negative group (p:0.006 CT: 0.84 ±0.23). According to the results of flow cytometry, CD8+CXCR5+PD1+ cell expression (%) levels were found to be significantly higher in patients (3.06 ±1.98) compared to the transplant control group (0,52±0,40) (p: 0.001) (Figure 1).

Conclusion: It shows that there may be a direct correlation between DSA and PD-1 / PDL-1 mRNA level and CXCR5+PD1+CD8+ follicular cytotoxic T cell in transplant patients after kidney transplantation.

COMPARISON OF EGFR CYSTATIN C AND EGFR CREATININE IN RECENTLY HOSPITALISED INDIVIDUALS

Kerry Horne1,2, Daniela Viramontes-Horner1, Rebecca Packington3, Sue Shaw2, Akeet Akani2, John Monaghan3, Tim Reilly4, Maarten Taal1,2 and Nick Selby1,2

1 University of Nottingham, Centre for Kidney Research and Innovation, Derby, United Kingdom, 2 University Hospitals of Derby and Burton NHS Foundation Trust, Renal Unit, Derby, United Kingdom, 3 University Hospitals of Derby and Burton NHS Foundation Trust, Department of Chemical Pathology, United Kingdom and 4 University Hospitals of Derby and Burton NHS Foundation Trust, Department of Informatics, United Kingdom

Background and Aims: Creatinine and cystatin C are endogenous biomarkers that can be used to estimate glomerular filtration rate (GFR). Cystatin C may be less dependent on age, gender and muscle mass. The comparative performance of these markers in recently hospitalised patients with acute kidney injury (AKI), who may have experienced changes in body composition, is unclear.

Method: Two matched cohorts of hospitalised individuals who had survived to 90 days after admission were recruited. The cohorts consisted of people who had sustained AKI during hospital admission and those who had not, and were matched 1:1 for age, baseline eGFR stage and diabetes. Serum creatine and serum cystatin C were measured at 3 months after hospitalisation and eGFR calculated using CKD EPI creatinine (eGFRcre) and CKD EPI cystatin C (eGFRcys) equations. Difference between the measures (eGFRdiff) was calculated as eGFRcys-eGFRcre and percentage difference (eGFR%diff) was relative to the mean of both eGFR measures. Primary outcome was mortality after 5 years of prospective follow up. Univariable survival analyses were conducted with the Kaplan Meier method and comparisons were performed with the log rank test, and a fully adjusted multivariable analysis performed with Cox proportional hazards model.

Results: 854 individuals were recruited, matched, and had paired creatinine and cystatin C measurements. 427 (50%) had sustained AKI. Median eGFRcys was lower than eGFRcre (53.5ml/min/1.73 m² [34.4-85.4] vs 68.4ml/min/1.73 m² [52.6-84.7], p<0.001). eGFRcys and eGFRcre were correlated (r =0.486, p<0.001) but Bland Altman analysis showed variable bias across the eGFR range. More individuals had an eGFR <60ml/min using eGFRcys (57%) compared with eGFRcre (35.6%). There was a graded relationship between eGFR%diff and outcome, with a shorter survival time (Figure 1) and higher proportion of deaths at 5 years (Q1 64 (30.0%), Q2 54 (25.4%), Q3 41 (19.2%), Q4 (31 (14.6%), p<0.001) in the first quartile. Cox proportional hazards analysis showed that eGFR%diff was an independent predictor of 5-year mortality after adjustment for age, Charlson index score and albuminuria (adjusted OR 0.995 [0.992-0.998], p = 0.002).

Conclusion: Cystatin C eGFR measures were lower than creatinine eGFR measures in recently hospitalised individuals. Lower eGFRcys relative to eGFRcre was independently associated with increased mortality. A larger difference between eGFRcys and eGFRcre may reflect loss of muscle mass (resulting in relatively lower serum creatinine) in somebody who has recently had an acute illness. Further, these results confirm how eGFRcre may overestimate kidney function and potentially miss patients with failed renal recovery at 3-months after AKI. The difference between eGFRcys and eGFRcre may be helpful in identifying people at greater risk of early mortality after an acute illness.
DETECTING NEONATAL AKI BY SERUM CYSTATIN-C

Xu Xin, Sheng Nie and Fan Fan Hou
Nanfang Hospital, Nephrology, Guangzhou, P.R. China

Background and Aims: Serum creatinine is not a sensitive biomarker for acute kidney injury (AKI) in neonates. Unlike creatinine, cystatin-C (Cys-C) does not cross the blood placental barrier and the serum level in the neonates is not significantly impacted by the gestation age, birthweight, and the age during the first four weeks after birth. Therefore, serum Cys-C may be a better marker neonatal AKI than serum creatinine. We aimed to assess the performance of serum Cys-C as an alternative biomarker for detecting neonatal AKI.

Method: This is a large multicenter cohort study including 52,333 hospitalized neonates. First, we assessed the impacts of gestational age, birthweight, and days after birth on the level of Cys-C, and estimated the upper normal limit (UNL) and the reference change value (RCV) of serum Cys-C in neonates. Then, we proposed a Cys-C based criteria (CyNA) for detecting neonatal AKI based on both Cys-C level and the change in Cys-C using UNL and RCV as the cutoffs, respectively. Finally, we assessed the performance of CyNA in detecting neonatal AKI and the association of CyNA-detected AKI with the risk of in-hospital death, and compared the performance with that using the KDIGO creatinine criteria.

Results: Cys-C level in neonates did not vary with gestational age and birthweight, and remained relatively stable during the neonatal period (Figure 1). The UNL of Cys-C was 2.2 mg/L and the RCV (for Cys-C ratio) was 1.25. CyNA criteria defines AKI by a serum Cys-C of ≥ 2.2 mg/L (UNL) or an increase in Cys-C of ≥25% (RCV) during the neonatal period. Among 52,333 neonates 6,336 (12.1%) AKI cases were detected by CyNA criteria, of whom 96 (1.5%) died. In comparison, 202 (0.44%) death events occurred in 45,997 neonates who did not have AKI. After adjusting all comorbidities, CyNA-detected AKI was associated with a significantly increased risk of in-hospital mortality (adjusted HR 2.91, 95% confidence interval, 2.24 to 3.78). Among 45,839 neonates that had measurement of both Cys-C and SCr, 4,513 (9.8%) had AKI detected by CyNA only, 373 (0.8%) by KDIGO only, and 381 (0.8%) by both criteria (Table 1). After adjusting admission to ICU and comorbidities, AKI detected by CyNA only (C-/+K-) was associated with a significantly increased risk of in-hospital mortality compared with those without AKI by both criteria (C-/K-), with an adjusted hazard ratio of 2.86 (95% CI, 2.02 to 4.04). In comparison, the HR for those detected by KDIGO only (C-/K+) was lower at 2.15 (95% CI, 0.96 to 4.81). Neonates with AKI detected by both criteria (C+/+K+) had the highest risk of in-hospital mortality (HR 4.86, 95% confidence interval, 2.84 to 8.29).

Conclusion: Serum Cys-C is a robust and sensitive biomarker for detecting neonatal AKI. CyNA is 5.5 times more sensitive than the modified KDIGO in detecting neonates who are at an elevated risk of in-hospital mortality.

*AKI status was presented as a combination of absence (-) or presence (+) of AKI detected by CyNA (C) and KDIGO (K) criteria, respectively. Hazard ratios were estimated in the neonates with measurements of both Cys-C and SCr using a Cox proportional hazard model with adjustment for gender, admission to ICU, and common comorbidities. AKI status and admission to ICU were coded as time-dependent covariates in the model.
Background and Aims: The possibility that population demographic characteristics, changes in viral strain and therapeutic advances in management of COVID-19 might influence clinical outcomes is of great interest given potential regional variations. The aim of our study was to describe regional variation in COVID-19 hospitalisation rates in England and factors affecting in-hospital mortality as well as acute kidney injury (AKI).

Method: In this retrospective cohort study using hospital episode statistics, we collected data from all adult hospitalised patients with COVID-19 infection (diagnostic code U07.1 in any of the 20 diagnoses codes) between 1st March 2020 and 31st March 2021, to end of discharge period. We also extracted all available secondary diagnoses and procedure codes. Patients with codes for chronic dialysis were excluded. We divided the observation period as per the dominant SARS CoV-2 variant and further, in relation to publication of the RECOVERY trial. SARS CoV-2 "Other" strain was prevalent between 1st March 2020 and 21st December 2020 and "Alfa" between 22nd December 2020 to 17th May 2021. The end date of each phase was based on more than 50% decline in each variant.

Results: We extracted 3,24,748 finished consultant episodes (FCE) for all patients with U071 code in any of the 20 diagnoses codes and admitted during the study period. After exclusion of multiple FCEs within same spell, chronic RRT and patients not residing in England, there were 749,844 unique admission spells with ICD10 code of U071 in one of the diagnoses codes in 337,029 patients. London had the highest number of COVID-19 admissions at 131,338 (18%) followed by North-west region with 122,683 admissions (16%). Population incidence of COVID-19 hospital admissions was highest in North-west at 21.167 per million population (pmp) and lowest in South-west at 9.292 admissions pmp. Patients with COVID-19 were younger (67.0 ± 17.7 years) in London as compared to patients in East of England (72.2 ± 16.8 years). Length of stay was lowest in North-east (12.2 ± 14.9 days) and highest in North-west (15.2 ± 17.9 days). As compared to London, all eight regions had higher odds of death, ranging from OR of 1.04 (95% CI 1.00, 1.07) in South-west to OR 1.24 (95% CI 1.21, 1.28) in North-west. Odds of death were lower in patients with COVID-19 in post-RECOVERY period, both with "Other" (OR 0.72, 95% CI 0.71, 0.74) and Alfa strain of SARS CoV-2 (OR 0.75, 95% CI 0.74, 0.76). Overall, AKI incidence was 30.3%. All eight regions in England had lower odds of developing AKI as compared to London. Post-RECOVERY periods with the "Other" variant (OR 0.87, 95% CI 0.85, 0.88) and "Alfa" variant (OR 0.87, 95% CI 0.86, 0.88) both had lower odds of developing AKI.

Conclusion: This large national study of COVID-19 found a higher hospital admission rate and AKI incidence but lower odds of death in London compared with other regions in England. The incidence of AKI and mortality due to any cause were lower in the post-RECOVERY period irrespective of the prevalent SARS CoV-2 strain.

Figure 1: Distribution of serum Cys-C and creatinine stratified by day after birth in the neonates.
Figure 1a: Mortality predictors in patients with COVID-19.
Background and Aims: Acute kidney injury (AKI) is a major complication in cancer patients receiving immune checkpoint inhibitors (ICIs). Previous studies have not accurately distinguished the various potential underlying causes of AKI due to the limited use of renal biopsy. Here, we reviewed cases of biopsy-proven acute tubulointerstitial nephritis (ATIN) in patients treated with ICIs to describe the clinical and laboratory characteristics and outcomes of this condition.

Method: We conducted a pooled analysis of clinical cases published up to 1 May 2022. The search terms on PubMed were [(Pembrolizumab OR Nivolumab OR Ipilimumab OR Atezolizumab OR Avelumab OR Durvalumab) AND (Nephritis)]. Only cases with biopsy-proven ATIN were included. Among a total of 111 patients identified, 83 were eligible for this analysis. We added two patients from our Institution. We collected data on clinical characteristics, renal biopsy findings, and laboratory examinations. AKI was graded according to the KDIGO criteria. As outcomes, we considered: complete renal recovery if serum creatinine returned to baseline +0.3 mg/dL, no recovery if patients needed dialysis and partial recovery in other cases.

Results: Overall, 85 patients (56 male) with an age of 61.4±19 years were evaluated. 43 patients (51%) had melanoma, 25 (30%) non-small cell lung cancer, 8 renal carcinoma, and 9 other cancers. ICI treatment consisted of PD-1, PDL-1 (nivolumab, pembrolizumab, atezolizumab) and CTLA4 inhibitors (i) (ipilimumab) or combination PD-1i-CTLA4i (Table 1). Renal toxicity developed after a median of four cycles of therapy, but in most cases (n = 59) after at least three treatment cycles. Eleven patients (14%) presented with AKI stage 1, 16 patients (20.5%) with stage 2, and 51 patients (65.5%) with AKI stage 3, including five patients requiring dialysis. Among AKI3 patients there was a significantly higher prevalence of patients at the first therapy line (p = 0.04), while all the 19 patients treated with the dual ICI blockade developed AKI3, compared with 29 patients out of the 52 taking a single agent (Figure 1A). Seventy-seven patients received steroids, while 7 patients did not receive any therapy. ICI treatment was withdrawn in 65 out of 69 patients with available data. Following AKI resolution, in 15 patients ICI was restarted, but in six (40%) AKI recurred. Overall, 32 patients (40%) presented a complete renal recovery, 45 patients (56.2%) had a partial recovery, and 3 patients (3.8%) did not recover. Among patients who did not fully recover, there was a higher prevalence of those treated with dual ICI blockade and presenting with AKI stage 3 (Figure 1B). At logistic regression, complete renal recovery was inversely associated with dual ICI blockade (OR 0.1, 95CI 0.02-0.5, p = 0.006) and AKI 3 (OR 0.31, 95CI 0.1-0.9, p = 0.04), but only the association with dual ICI therapy remained significant at multivariate analysis.

Conclusion: ICI-related ATIN may develop late after the initiation of therapy. It may present as a severe form of AKI, particularly in patients with dual ICI blockade. Although this complication may be partially reversible, concerns

EPIDEMIOLOGY AND OUTCOMES OF ACUTE KIDNEY INJURY: DON’T FORGET THE CHILDREN
Flavia Chisavu, Ramona Stroescu, Lazar Chisavu, Mihai Gafencu and Adalbert Schiller
University of Medicine and Pharmacy ‘Victor Babes’ from Timisoara, Romania, Timisoara, Romania

Background and Aims: Acute kidney disease (AKI) has evolved from a primary single renal disease to a syndrome secondary to other systemic illness. The aim of this study is to assess AKI epidemiology in a large East European country database comprising a mixt paediatric population (critically ill and non-critically ill) and the impact on mortality and hospitalization length.

Method: We conducted a retrospective observational study on all the admitted paediatric patients from 1 day to 18 years old between first of January 2014 until the 31 December 2021. Out of 137760 admissions, 2194 patients were included in the study. We classified the different age groups as: premature (all the babies born before 37 weeks of gestation), full-term new-borns, infants (between 28 days and 12 months of life), toddlers (over 12 months up to 3 years), preschoolers (between 3 and 5 years), scholars (6 years to 11 years) and adolescents (12 to 18 years).

Results: The overall incidence of AKI was 15.92/1000 hospital admissions with a 4.77 times fold increased incidence over the 8 year period, from 6.72 in 2014 to 32.12/1000 admissions in 2021. The most prevalent age group, accounting for almost half the AKI cohort (49.49%), was represented by the neonatal setting with 527 (24.02%) preterm and 539 (25.47%) full-term neonates. The paediatric age groups were represented by 10.84% infants, 8.29% toddlers, 6.65% pre-schoolers, 10.57% school aged children and 14.17% adolescents. Staging AKI according to AKIN, stage 1 was identified by us in 24.24% of the AKI cases, stage 2 in 31.03% and stage 3 in 44.71%. Only 25 patients (1.1%) required RRT. Dividing the cases by AKI causes, the most common was represented by prerenal AKI in 85.64% of the cases, followed by 12.16% renal causes respectively 2.18% postrenal causes. Over the 8-years period, from the 137 760 admitted children, 0.32% (449 patients) died of whom 255 (56.79%) presented AKI diagnosis. The risk of death in the presence of AKI was 109 times higher than in the no-AKI group (p < 0.0001, 95% CI: 90-132), mortality in the AKI group being 11.62%. Stage 3 AKI group had a higher risk of death than stage 1 with an OR of 3.31 (CI = 2.516-4.355, p < 0.001). The average hospitalization period for all admitted patients (137 760) was 5.76 days. In the presence of AKI the average hospitalization period increased to 20.9 days ± 19.3 days.

Conclusion: The neonatal setting portends poor outcomes with the highest incidence of AKI. We can state that in the 21st century patients do no die of AKI but with AKI. Hospitalization increased significantly in the presence of AKI.

INCIDENCE, RISK FACTORS, AND OUTCOMES OF ACUTE LIVER INJURY IN HOSPITALIZED ADULTS WITH ACUTE KIDNEY INJURY: A LARGE MULTICENTER STUDY
Lin Yuxin, Jiao Liu, Sheng Nie and Xu Xin
P.R. China

Background and Aims: Acute kidney injury (AKI) and acute liver injury (ALI) were associated with poor outcomes during hospitalization, respectively. However, the clinical outcome of AKI combined with ALI (AKI-ALI) was still remains unknown. The current study was aimed to describe the incidences, risk factors, and outcomes of AKI-ALI.

Method: The study population included AKI patients aged 18–99 years with enough serum creatinine testing and liver function testing (LFT) hospitalized at 19 medical centers throughout China between 2000 and 2021. AKI was defined by Kidney Disease Improving Global Outcomes and ALI was defined by the change of liver enzymes based on Asia Pacific Association of Study of Liver consensus guidelines. The Cox proportional hazards model was used to identify risk factors for AKI-ALI, and a time-dependent Cox proportional hazards regression model was used to estimate the association between AKI-ALI and in-hospital mortality.

Results: Among the 18461 patients with AKI (median [Interquartile Range, IQR] age, 65.71 [52.78, 76.36] years, 9725 (52.7%) males), ALI occurred in 1689 (9.1%) patients. Patients with AKI who were male, have used drugs including antibiotics, diabetes agents, diuretics, glucocorticoids, immunosuppressants, nonsteroidal anti-inflammatory drugs or vasopressors, with heart failure, respiratory failure, malignant tumor or shock, have lower platelets levels, higher aspartate aminotransferase levels or higher glutamyl transpeptidase levels at baseline, have received general surgery or thoracic surgery were associated with higher risk of AKI-ALI. Patients with AKI-ALI had longer length of hospital stay and were associated with a higher risk of in-hospitalized mortality (Hazard ratio [95% Confidence Interval] 1.51, [1.33, 1.72]) compared with patients with AKI but without ALI. In addition, a stronger association between AKI-ALI and in-hospital mortality was found in those with lower AKI grades (P for interaction = 0.036).

Conclusion: ALI was common among patients with AKI and AKI-ALI was associated with an increased risk of in-hospital mortality. This study suggests interventions for liver function early to improve in-hospital prognosis of patients with AKI.

ACUTE KIDNEY INJURY AS A RISK FACTOR FOR THE DEVELOPMENT OF CHRONIC KIDNEY DISEASE AND MORTALITY IN HOSPITALIZED PATIENTS

Julio Francisco Colina García, Lucía Cordero García-Galán, Marta Rivero Martínez, Paúl Hernández, Celia González-García, Sergio Huerga Lozano, Justo César Sandino Pérez, Pilar Auñón, Eduardo Gutiérrez and Enrique Morales

University Hospital October 12, Nephrology, Madrid, Spain

Background and Aims: Acute kidney injury (AKI) is a complication that affects more than 5% of all hospital admissions and up to one third of patients admitted to critical care units. This entity, whose incidence is on the rise, remains a major cause of morbidity and mortality. In addition, AKI has been linked as an independent risk factor for mortality, especially in severe forms, and of those patients who survive, a percentage will develop chronic kidney disease (CKD) during follow-up. We conducted this study to analyse the incidence of CKD at 6 and 12 months follow-up in hospitalized patients with AKI, to identify possible risk factors leading to its development and to determine mortality in this group of patients.

Method: This is a retrospective study of a cohort of cases with AKI (baseline eGFR > 60 mL/min/1.73 m² without previous structural damage) from our hospital, taking place from June 2020 to February 2021. Regarding the evolution of the AKI, four possibilities were considered: recovery of normal kidney function, development of CKD at 6 months, development of CKD at 12 months or death during follow-up.

Results: We studied 148 patients (55% male), with a median age of 83 years (74-87). Thirty-six patients (24.3%) developed CKD at 6 months follow-up and 30 patients (20.3%) at 12 months. Forty-one patients (27.7%) died within the first 12 months following an episode of AKI. The risk factors identified for development of CKD at 12 months were older age (85 vs 77; p = 0.03), higher serum lactate dehydrogenase levels at admission (246 U/L vs 201 U/L; p = 0.04) and at 3 months (252 U/L vs 192 U/L; p = 0.039), and eGFR < 60 mL/min/1.73 m² at 1 week (74.5 vs 57; p = 0.004) and at 3 months (79 vs 50; p < 0.001) of follow-up. Identified risk factors and predictors of AKI-associated mortality were older age (84 vs 80.5; p = 0.018), concomitant oncological pathology (10.8% vs 7.4%; p = 0.018), higher Charlson index (6 vs 5; p < 0.001), higher AKI stage (p = 0.042), lower serum albumin levels at first (3.35 g/dL vs 3.90 g/dL; p = 0.014) and at third month (3.2 g/dL vs 4 g/dL; p < 0.001) of follow-up.

Conclusion: Our study showed a high incidence of CKD in patients who have had an episode of AKI. Several risk factors for development of CKD were identified, being the older age and the greater length of recovery period from AKI the most useful predictors in the clinical practice. AKI-associated mortality was very high in those older patients with higher comorbidity and persistence of AKI. Despite advances, we need non-classical biomarkers for early diagnosis and more effective therapeutic measures to avoid this high prevalence of CKD and mortality.

ASSOCIATION BETWEEN TRANSIENT AKI AND ALL-CAUSE MORTALITY IN PATIENTS WITH CRITICAL ILLNESS: AN INTERNATIONAL MULTICENTRE RETROSPECTIVE COHORT STUDY

Pang Mingzhen1, Sheng Nie1,2 and Fan Fan Hou1

1Guangzhou, P.R. China and 2P.R. China

Background and Aims: Transient acute kidney injury (AKI) is common in critically ill patients. However, the effect of transient AKI on prognosis of patients remains controversial. We aimed to investigate the association of transient AKI with all-cause mortality and kidney outcomes in critically ill patients.

Method: We conducted a multicentre retrospective cohort study involving 40168 critically ill patients from CRDS and 8657 patients from MIMIC-IV databases. Among them, 10147 patients were diagnosed as AKI according to KDIGO criteria and classified into transient (duration ≤ 48 h) and persistent (duration > 48 h). The study outcomes included mortality in hospital, by day 30 and up to 1 year, and risk of progression to CKD. We determined the effect of transient AKI on mortality by Cox regression model adjusting for confounding variables and analyzed CKD incidence by Fine-Gray model adjusted for difference in biologically plausible confounders.

Results: AKI occurred in 20.8% of 48825 critically ill patients, of which 36.4% was classified into transient and 63.6% persistent. Compared with those without AKI, Patients with transient AKI were older, more often received diuretic therapy and sedative therapy, and higher Charlson comorbidity index. After adjusting confounders including AKI severity, transient AKI was independently associated with increased risk of hospital death (HR 1.97, 95% CI 1.68 to 2.31), 30-day mortality (HR 1.73, 95% CI 1.51 to 1.98) and 1-year mortality (HR 1.31, 95% CI 1.19 to 1.44). Meanwhile, the risk of all-cause mortality increased with the duration of AKI in those with persistent patients (P < 0.05). Among survivors without history of CKD, compared with patients without AKI, transient AKI was also associated with increased risk of incident CKD after discharge (HR 1.61, 95% CI 1.33 to 1.96).

Figure 1: The hazard ratios of clinical outcomes among patients at different stages and durations of AKI. Hazard ratio were estimated using a Cox proportional hazard model with adjustment for gender, age, ethnicity, RASS, diabetes drugs, diuretics, NSAID, pressor, Scr, cardiac surgery, neurology, cerebral bleeding, cerebral infarction, CHD, CKD, congestive heart failure, diabetes, hypertension, sepsis, Charlson comorbidity index.

**INNOVATIVE METHOD TO EVALUATE MATURATION OF NEWLY CREATED ARTERIO-VENOUS FISTULAS: INSIGHTS FROM A QUALITY IMPROVEMENT PROJECT**

Laura Rosales Merlo¹, Xiaoling (Janice) Ye¹, Hanjie Zhang¹, Brenda Chan¹, Marilou Mateo¹, Frank Van Der Sande¹², Jeroen Kooman¹³ and Peter Kotanko¹

¹Renal Research Institute, New York, United States of America, ²Maastricht University Hospital, Nephrology, Netherlands and ³Maastricht University Hospital, Nephrology, Netherlands

**Background and Aims:** Recently, we introduced central-venous oxygen saturation (ScvO2) and estimated upper-body blood flow (eUBBF) to monitor the maturation of newly created arterio-venous fistulas (AVF) in hemodialysis (HD) patients [1]. The approach was implemented in a clinical quality improvement project (QIP).

**Method:** The QIP involved two Renal Research Institute dialysis centers in New York City that use the Crit-Line monitor (CLM, Fresenius Medical Care, Waltham, MA, USA) as part of the standard of care. CLM measures automatically and non-invasively hematocrit and oxygen saturation (i.e., ScvO2 in patients with central venous catheter as vascular access). eUBBF was computed as described previously [1]. Patients with a with a newly created AVF were included, irrespective of their HD vintage. The QIP team comprised a registered nurse per clinic, two research physicians, and two data analysts. The team met weekly to assess the AVF maturation progress based on eUBBF and ScvO2 data that were displayed on a specific dashboard. Successful AVF maturation is typically accompanied by a rise in cardiac output and eUBBF that starts immediately after AVF creation. However, it is unknown what degree of eUBBF increase indicates a subsequently successful AVF maturation. To identify predictive eUBBF thresholds, we correlated eUBBF changes with the progress of AVF maturation in the six weeks following AVF creation. We defined maturation as unsuccessful when the newly created AVF required an intervention (e.g., angioplasty) or was abandoned.

**Results:** We studied 39 patients (age 56 ± 18 years; 25 males). Twenty-eight of them were incident patients. Two patients had a second AVF created. In 15 patients AVF maturation was unsuccessful. In these patients, eUBBF increased to an average of 119.2% (SD 35.2) compared to pre-AVF creation. In patients with successful AVF maturation (N = 24), eUBBF increased to an average of 153.7% (SD 31.6) (Figure 1). The difference between the groups is 34.4 percentage points (95% CI: 12.4 to 56.4; p = 0.003). Using eUBBF as a diagnostic measure to discriminate successful vs. failed AVF maturation, an area under the receiver operating characteristics curve of 0.824 (95% CI: 0.673 to 0.973; p = 0.001) was obtained. An eUBBF increase of 25% had a sensitivity of 59% and a specificity of 92% to predict AVF maturation outcomes.

**Conclusion:** Computation of eUBBF provides a simple and non-invasive means to track AVF maturation and predict its outcomes.

**REFERENCE**

**Figure 1:** Estimated upper body blood flow (eUBBF) in the six weeks after AVF-creation, expressed as % of pre-AVF creation eUBBF. The left box and whisker plot shows failed AVF maturations (N = 17; median 125.6%, IQR 92.9 – 134.3), the right successful ones (N = 24; median 146.7%, IQR 132.8 – 170.1). *Two patients had a second AVF created.*
ASSOCIATION BETWEEN NEPROLITHIASIS AND KIDNEY DISEASE PROGRESSION IN AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE PATIENTS: A PROSPECTIVE COHORT STUDY
Hongran Moon1,2, Hyunjin Ryu1, Yong Chul Kim1,2, Hayne Cho Park1, Kook-Hwan Oh1,2, and Yun Kyu Oh1,4
1Seoul National University College of Medicine, Department of Internal Medicine, Seoul, Rep. of South Korea, 2Seoul National University Hospital, Department of Internal Medicine, Seoul, Rep. of South Korea, 3Hallym University Kangnam Sacred Heart Hospital, Department of Internal Medicine, Seoul, Rep. of South Korea and 4Department of Internal Medicine, Seoul Metropolitan Government Seoul National University Borame Medical Center, Seoul, Rep. of South Korea

Background and Aims: Nephrolithiasis is a common complication in Autosomal dominant polycystic kidney disease (ADPKD) patients and is known to occur in up to 8% to 36% of the patients. A few in vitro and in vivo studies showed that kidney and ureter stone formation could accelerate renal disease progression in ADPKD. However, its association between nephrolithiasis and renal function deterioration remains unknown in ADPKD patients.

Methods: This is a study from single center prospective cohort called HOPE-PKD. A total of 410 study subjects with abdominal computed tomography (CT) scan within 1 year before the enrollment were analyzed. Study subjects were divided into two groups according to the CT results as follows: Patients with papillary calcification, calyceal stone, ureter stone, or renal stone were classified as a stone group and those without any stones were classified as no-stone group. Each was manually inspected. Patients were excluded who were not suitable for inclusion (e.g. paediatric data, incomplete records, patients without relevant diagnoses). Non-parametric Kruskal Wallis testing was used via R statistical software.

Results: There was no difference in the baseline characteristics between the stone group and the no-stone group. During a median 5.18 (interquartile range 3.41 - 8.03) year of follow-up, the primary and secondary outcomes occurred in 51 (12.4%) and 96 (23.4%) patients, respectively. In the unadjusted Cox regression analysis, there was no significant difference in the survival analysis between the two groups. However, after adjusting possible confounding factors (age, sex, body mass index, eGFR, comorbidity of hypertension and diabetes, serum uric acid, phosphorous and calcium level, results of PKD1 and PKD2 gene analysis, and Mayo classification), the stone group showed an increased risk of the primary and secondary outcome of HR 2.84 (95% CI 1.26 - 6.38; p-value 0.012) and HR 1.83 (95% CI 1.03 - 3.27; p-value 0.041), respectively compared to the no-stone group (Figure 1).

Conclusion: This is the first prospective cohort study showing that nephrolithiasis is associated with poor renal outcomes in patients with ADPKD. Further clinical studies of nephrolithiasis in ADPKD patients are warranted to improve renal outcomes.

Figure 1: The survival graph of composite renal outcome from multivariate Cox regression analysis. After adjusting with baseline age, sex, body mass index, estimated glomerular filtration rate, comorbidity of hypertension and diabetes, serum uric acid, phosphorous, calcium level, results of PKD1 and PKD2 gene analysis, and Mayo classification, there was significant risk increased in the stone group compared to the no-stone group with hazard ratio of and HR 1.83 (95% CI 1.03 - 3.27; p-value 0.041).

THE WEST OF SCOTLAND AND THROMBOTIC MICROANGIOPATHY
Ciaran Groome and Neal Padmanabhan
Queen Elizabeth University Hospital, Nephrology, Glasgow, United Kingdom

Background and Aims: Thrombotic microangiopathy (TMA) is a diagnosis made on tissue biopsy manifesting as acute organ dysfunction. It has a variety of causes broadly categorised as: primary hereditary/genetic, primary acquired, secondary, and infection-related [1]. On blood testing there is evidence of microangiopathic haemolytic anaemia (MAHA) –, thrombocytopenia, raised lactate dehydrogenase (LDH), reduced haptoglobin and fragments on blood film. Renal involvement with acute injury is evidenced by an elevation in creatinine; together with MAHA this is haemolytic uraemic syndrome (HUS). We sought to examine the TMA/MAHA population as it presented to nephrology in the West of Scotland and evaluate if there was differences in presentation between TMA with and without MAHA.

Method: This is a retrospective case series of adult nephrology patients. We extracted health data from the west of Scotland renal electronic patient records database Strathclyde Electronic Renal Patient Record (“SERPR”) provided by VitalDataClient. We ran a query to identify patients in whom TMA and/or MAHA and/or HUS was inputted as a diagnosis. 363 patients were identified. Each was manually inspected. Patients were excluded who were not suitable for inclusion (e.g. paediatric data, incomplete records, patients without relevant diagnoses). Non-parametric Kruskal Wallis testing was used via R statistical software.

Results: 134 patients were identified. The underlying diagnoses were: hypertension (n = 34), the atypical HUS (aHUS, n = 22), drug-induced (n = 17), autoimmune (n = 12), thrombotic thrombocytopenic purpura (n = 12), malignancy (n = 10), inflammatory (n = 10), peri-partum (n = 9). Others included: transplant-related, unknown, Ecoli 0157, diarrhoea-related, IgA, AAV, MPGN, and essential thrombocthyemia. Note: many patients had
multiple possible contributors to their diagnosis. The average biochemical levels at presentation were: creatinine 591umol/L; haemoglobin 82; platelet count 98.7; LDH 1674.2; bilirubin 34.5. Renal recovery was observed in n = 27 (19%); CKD3 n = 32 (24%); CKD4 n = 10(7%); CKD5 n = 7(5%); those who have progressed to ESRF (requiring renal replacement therapy) n = 40(31%); persisting transplant function n = 5(4%). 15 patients died (10%). We categorised patients into 3 groups. 1 – presence of TMA on biopsy without MAHA (n = 28). 2 – TMA on biopsy plus evidence of MAHA (n = 41). And 3 – MAHA in those not biopsied (n = 62). 3 patients with MAHA did not have TMA on biopsy. Those in group 1 had on average a lower serum creatinine at 331umol/L compared with group 2 (634 umol/L) and group 3 (666 umol/L). This result was significant p <0.05. Hypertension was a leading cause in groups 1 and 2. aHUS was not present in group 1 - all patients presented with MAHA. All peri-partum patients were in group 3 i.e. not biopsied.

Conclusion: It is evident from the dataset that hypertension is a major contributor to acute and chronic renal impairment. With aHUS contributing to a significant number of cases, given the advances in testing and therapeutics, early liaison with national services in complement disorders is paramount to protecting the kidneys. With 19% of patients regaining an eGFR >60ml/min prompt investigation is crucial to reducing the burden of disease. Long term renal follow-up should be offered. 21% of patients had no evidence of MAHA –we should be wary of excluding a TMA process in the absence of MAHA.

Method: Retrospective cohort study, analyzing data of 413 hospitalized adult patients. Immunosuppressed patients have been excluded. Descriptive analysis was done with t-test, Mann-Whitney and Fisher test. Mediation analysis was done modelling time-to-HAI through a Cox regression, including AKI as the exposure of interest, the use of medical devices as mediator, and age, diabetes and multimorbidity as confounders.

Results: Clinical characteristics of patients are shown in Table 1. AKI patients resulted more fragile and with a higher frequency of HAI (10.8% vs 5.9%, p = 0.07). Univariate logistic regression showed that the presence of urinary catheter (OR 5.053, 95% CI 2.040-12.520) and a longer hospital stay (OR 1.115, 95% CI 1.075-1.157) were risk factors for the development of HAI. Compared to other AKI etiologies, intrinsic AKI had a significantly higher frequency of HAI (38.5%, p<0.01) (Fig. 1). HAI frequency also increased progressively with increasing AKI stage (15.2% in stage I-II and 6.4% patients without AKI or stage I, p = 0.01) (Fig. 1). From the Cox regression model, none of the variables showed an independent association with HAI (Table 2). The total effect of AKI on HAI development was estimated in a HR of 0.970 (95% CI 0.438-3.016). Part of this effect was found to be mediated by the medical devices (HR 1.155, 95% CI 0.982-1.393), while the direct effect of AKI was a HR of 0.840 (95% CI 0.352-2.411).

Conclusion: AKI patients are more fragile and have a higher frequency of HAI, especially in intrinsic and stage II-III AKI. However, we didn’t observe an independent effect of AKI on the development of HAI. Further research is needed.

HOSPITAL-ACQUIRED INFECTIONS IN HOSPITALIZED PATIENTS WITH ACUTE KIDNEY INJURY: A RETROSPECTIVE COHORT STUDY

Francesco Reggiani1,2, Marta Calatroni1,2, Claudio Angelini2 and Salvatore Badalamenti2

1 Humanitas University, Department of Biomedical Sciences, Milan, Italy and 2 IRCCS Humanitas Research Hospital, Nephrology and Dialysis Unit, Milan, Italy

Background and Aims: Acute kidney injury (AKI) is recognized as a systemic disease that leads to several complications, including infections. However, only few studies have investigated the relationship between AKI and subsequent development of hospital-acquired infections (HAI). The aim of this study was to evaluate this relationship.
Figure 1: HAI incidence in patients with AKI, according to stage and cause of AKI. Intrinsic AKI has significantly higher frequency of HAI (38.5%, p<0.01). HAI frequency also increased progressively with increasing AKI stage.
Background and Aims: Multiple myeloma (MM) is the 2nd most common haematological neoplasm and a largely heterogeneous malignancy in what regards cytogenetics, clinical presentation, therapy response and overall survival. Renal impairment related to MM is known to be diagnosed in at least 50% of patients during the course of this disease. Recent studies have shown an association between high-risk cytogenetic abnormalities (CA) with lower disease-free survival and lower overall survival. However, there is still scarce knowledge in what regards the kidney implications of MM CA. The purpose of this study is to identify an association between MM cytogenetic profile and acute kidney injury (AKI) at presentation.

Method: This was a single-centre retrospective cohort study of all adult patients diagnosed with MM between Jan./2018-Dec./2021 in a tertiary care university hospital in Lisbon. Diagnosis of MM was made according to the International Myeloma Working Group criteria. Patient variables were collected from individual clinical records. Categorical variables were described as the total number and % and continuous variables as median (P25-P75). Normally distributed continuous variables were compared with the Student-t-test, non-normally distributed continuous variables with the Mann-Whitney U-test and categorical variables with the chi-squared test. A multivariable backward stepwise regression model was performed to investigate predictors for AKI. Statistical significance was defined as p < 0.05. Analyses were performed with the statistical software package STATA 16.0.

Results: 114 patients were included (median age 69.8±11.4 years, 48.1% male, 90.4% caucasian). 61.5% had hypertension, 21.2% diabetes and 33.9% CKD. 50% of patients during the course of this disease. Recent studies have shown an association between high-risk cytogenetic abnormalities (CA) with lower disease-free survival and lower overall survival. However, there is still scarce knowledge in what regards the kidney implications of MM CA. The purpose of this study is to identify an association between MM cytogenetic profile and acute kidney injury (AKI) at presentation.

Conclusion: Our study suggests there is an association between CA and AKI at presentation, which may implicate a worse overall survival, have treatment implications and highlights the need for prevention and early diagnosis. MM cytogenetics is being studied since the 2000s and research is still on going in the attempt of creating a MM profile that can guide prevention, treatment and predict outcomes. It is known that renal impairment in MM particularly at diagnosis is associated with lower overall survival. However, to the best of our knowledge, the potential association between cytogenetic profile and AKI has not been thoroughly studied.

ACUTE KIDNEY INJURY AND MULTIPLE MYELOMA-THE ROLE CYTOGENETICS: A COHORT STUDY
Natacha Rodrigues1, Carolina Branco1, Guilherme Sapinho3, Joana Vieira2, Hugo Silva1, Carlos Martins2, Graça Esteves2, João Raposo3 and José António Lopes4
1 Centro Hospitalar Universitário Lisboa Norte, EPE, Nephrology and Renal Transplantation, Lisbon, Portugal and 2 Centro Hospitalar Universitário Lisboa Norte, EPE, Hematology, Lisbon, Portugal

Background and Aims: Multiple myeloma (MM) is the 2nd most common haematological neoplasm and a largely heterogeneous malignancy in what regards cytogenetics, clinical presentation, therapy response and overall survival. Renal impairment related to MM is known to be diagnosed in at least 50% of patients during the course of this disease. Recent studies have shown an association between high-risk cytogenetic abnormalities (CA) with lower disease-free survival and lower overall survival. However, there is still scarce knowledge in what regards the kidney implications of MM CA. The purpose of this study is to identify an association between MM cytogenetic profile and acute kidney injury (AKI) at presentation.

Method: This was a single-centre retrospective cohort study of all adult patients diagnosed with MM between Jan./2018-Dec./2021 in a tertiary care university hospital in Lisbon. Diagnosis of MM was made according to the International Myeloma Working Group criteria. Patient variables were collected from individual clinical records. Categorical variables were described as the total number and % and continuous variables as median (P25-P75). Normally distributed continuous variables were compared with the Student-t-test, non-normally distributed continuous variables with the Mann-Whitney U-test and categorical variables with the chi-squared test. A multivariable backward stepwise regression model was performed to investigate predictors for AKI. Statistical significance was defined as p < 0.05. Analyses were performed with the statistical software package STATA 16.0.

Results: 114 patients were included (median age 69.8±11.4 years, 48.1% male, 90.4% caucasian). 61.5% had hypertension, 21.2% diabetes and 33.9% CKD. 50% of patients during the course of this disease. Recent studies have shown an association between high-risk cytogenetic abnormalities (CA) with lower disease-free survival and lower overall survival. However, there is still scarce knowledge in what regards the kidney implications of MM CA. The purpose of this study is to identify an association between MM cytogenetic profile and acute kidney injury (AKI) at presentation.

Conclusion: Our study suggests there is an association between CA and AKI at presentation, which may implicate a worse overall survival, have treatment implications and highlights the need for prevention and early diagnosis. MM cytogenetics is being studied since the 2000s and research is still on going in the attempt of creating a MM profile that can guide prevention, treatment and predict outcomes. It is known that renal impairment in MM particularly at diagnosis is associated with lower overall survival. However, to the best of our knowledge, the potential association between cytogenetic profile and AKI has not been thoroughly studied.

INCIDENCE AND PROGNOSIS OF HYponATREMIA IN HOSPITALIZED PATients WITH ALCOHOLIC LIVER DISEASE
Tae Won Lee1,2,3, Seoje Lee1,2, Jun Ha Ryu1, Eunjin Bae1,2,3 and Dong Jun Park1,2,3
1 Gyeongsang National University College of Medicine, Jinju, Department of Internal Medicine, Jinju-si, Rep. of South Korea, 2 Gyeongsang National University, Institute of Health Science, Jinju-si79, Rep. of South Korea and 3 Gyeongsang National University Changwon Hospital, Division of Nephrology, Department of Internal Medicine, Changwon-si, Rep. of South Korea

Background and Aims: Hyponatremia is a common electrolyte disorder in hospitalized patients and has a poor prognosis leading to an increased risk of poor quality of life, morbidity, and mortality. Although the prevalence and prognosis of hyponatremia in early liver disease or alcoholic liver disease (ALD). Therefore, the purpose of this study was to investigate the prevalence and prognosis of hyponatremia in ALD group.

Method: We performed a retrospective, single centre study of patients admitted to the hepatology department from March 2016 to December 2022. Adults aged 18 years or older were included, and patients with liver cirrhosis, one of the common causes of hyponatremia, were excluded from the study. Based on the electronic medical records, the study was conducted by dividing the ALD group including alcoholic hepatitis and heavy alcohols into a control group.

</tbody>
</table>

Results: A total of 830 patients were included, hyponatremia (under 135 mmol/L) occurred in 32.2%, and the ALD group showed a significantly higher prevalence than the control group (53.8% vs. 28.6, p<0.001). In addition, the ALD group was statistically significantly higher than the control group in mortality at hospitalization (8.4% vs. 3.9%, p = 0.031) and all-cause mortality (22.7% vs. 12.1%, p = 0.002). The length of hospital stay was significantly longer (13.5±10.9 vs. 10.5±9.1, p = 0.006), and the readmission rate was also higher in the ALD group (39.5% vs. 22.5%, p < 0.001). Kaplan-Meier analysis revealed significantly higher overall survival in the control group than the ALD group (87.9% vs. 77.3% p = 0.002).

Conclusion: Our study shows that ALD has a higher incidence rate of hyponatremia, which is followed by a poor prognosis, such as an increase in readmission rates, length of hospitalization, and mortality. Therefore, clinicians should realize the importance of electrolyte imbalance in ALD patients and strive to improve prognosis through early and appropriate treatment.

Licong Su, Yanqin Li, Ruqi Xu, Qi Gao, Ruixuan Chen, Xiaodong Zhang, Fan Luo, Sheng Nie and Xu Xin
National Clinical Research Center for Kidney Disease, State Key Laboratory of Organ Failure Research, Nanfang Hospital, Southern Medical University, Guangzhou, China, Division of Nephrology, Guangzhou, P.R. China

Background and Aims: Acute kidney injury (AKI) has been associated with increased risks of new-onset and worsening proteinuria. However, the epidemiologic data of post-AKI proteinuria was still lacking. This study aimed to determine the incidence, risk factors and clinical correlations of post-AKI proteinuria among hospitalized patients.

Method: This study conducted a multicenter cohort from Chinese Renal disease Data System (CRDS), including patients aged 18–100 years with hospital-acquired AKI (HA-AKI) hospitalized at 19 medical centers throughout China. AKI was defined according to the Kidney Disease Improving Global Outcomes (K/DOQI) creatine criteria. The results of both quantitative and qualitative urinary protein tests were used to determine post-AKI proteinuria. The primary outcome was the incidence of post-AKI proteinuria. Secondary outcomes included AKI recovery and kidney disease progression. Cox proportional hazard model with stepwise regression was used to determine the risk factors for post-AKI proteinuria. The associations of post-AKI proteinuria with kidney disease progression were analyzed by logistic regression models.

Abbreviations: HA-AKI, Hospital Acquired-Acute Kidney Injury; hospital-acquired acute kidney injury; CKD, Chronic Kidney Disease; OR, Odds ratio; CI, Confidence Interval; Ref., Reference.
aAdjusted for age, sex, status of drinking and smoking, baseline eGFR, ICU admission, CCI, stage AKI, hospital, division, hypertension, and diabetes.

Results: Of 6,206 HA-AKI patients without proteinuria at baseline, 2,102 (33.9%) had new-onset proteinuria, whereas, of 5,137 HA-AKI with baseline proteinuria, 894 (17.4%) had worsening proteinuria after AKI (Table 1). Higher AKI stage and preexisting CKD diagnosis were risk factors for new-onset proteinuria and worsening proteinuria, whereas treatment with RAS inhibitors was associated with an 11% lower risk of incident proteinuria. About 60% and 75% of patients with post-AKI new-onset and worsening proteinuria, respectively, recovered within 3 months. Worsening proteinuria was associated with a lower incidence of AKI recovery and a higher risk of kidney disease progression (Table 2).

Conclusion: Post-AKI proteinuria is common and usually transient among hospitalized patients. The risk profiles for new-onset and worsening post-AKI proteinuria differed markedly. Worsening proteinuria after AKI was associated with adverse kidney outcomes, which emphasized the need for close monitoring of proteinuria after AKI.

SEX AND CARDIOVASCULAR DISEASE IN STAGE G2-5 CKD PATIENTS

Francesca Mallamaci1,2, Pasquale Fabio Provenzano2, Giovanna Parlongo1, Daniela Leonardis2, Graziella Caridi3, Francesco Marino1, Graziella D’arrigo6, Giovanni Luigi Tripepi2 and Carmine Zoccali1,4,5

1Nephrology, Dialysis and Transplantation Unit, GOM BMM, Reggio Calabria, Italy; 2IHC-CNR, Section of Reggio Calabria, Reggio Calabria, Italy; 3Renal Research Institute, New York, United States of America; 4BIOGEM, Ariano Irpino, Italy and 5IPNET, Reggio Calabria, Italy

Background and Aims: Male sex is considered a major risk factor for cardiovascular (CV) disease in the general population, but the role of this factor in the high risk for CV disease in the pre-dialysis CKD population is still debated.

Methods: We tested the relationship between sex and fatal and non-fatal major CV events (myocardial infarction, heart failure, arrhythmia, angina, stroke, transient ischemic attack, peripheral vascular disease, major arterial or venous thrombotic episodes and sudden death) in a cohort including 759 stage 2-5 CKD consecutively recruited from 22 Nephrology units in southern Italy between October 2005 and September 2008. After the initial assessment, patients were followed up for a median time of 36 months (range 0.3–48 months).

Results: Four hundred fifty-five patients were males (60%). The proportion of smokers was about 4 times higher in males (71.4%) than in females (17.4%). Males and females differed in the prevalence of diabetes (38.5% versus 29.6%) and the frequency of background CV comorbidities (35.6% versus 19.7%, P<0.001). Waist circumference (100.9±12.4 versus 96±14.1 cm), eGFR (37.5±13.4 versus 33±12.7 ml/min/1.73 m²), 24-hour urinary protein excretion (median: 0.7 g/24h, IQR: 0.2-1.6 g/24h versus 0.5, IQR: 0.2-1.2 g/24h), and haemoglobin (13.4±1.9 versus 12±1.4 g/dL) were higher in males than in females. Serum phosphate (3.6±0.75 versus 3.9±0.75 mg/dL), hs-CRP (median: 2.2 mg/dL, IQR: 1.4-7.4 mg/dL versus 2.8 mg/dL, IQR: 1.2-6.4 mg/dL) and total cholesterol (178±3±42.1 versus 198±8±45.6 mg/dL) were lower in males than in females. During follow-up, 42 patients died, and 118 had fatal and non-fatal CV events. On univariate Cox regression analyses, male gender failed to be associated with all-cause mortality but was strongly related to the incidence rate of fatal and non-fatal major CV events [HR 1.75, 95% CI: 1.18-2.60, P=0.006]. Data adjustment for a series of major potential confounders did not materially affect the strength of this relationship [HR 1.78, 95% CI: 1.18-2.60].

Figure 1:
1.03-3.09). Further analysis testing the effect of age on major CV outcomes by gender showed an effect modification by this risk factor on the same outcome (P=0.037) because the hazard ratio of male versus female CV events increased progressively with ageing (Figure 1).

Conclusion: The excess risk for CV mortality by the male gender in the general population holds in stage G2-5 CKD patients. Age is a modifier for the excess risk for CV events in CKD patients because the risk excess of the male gender increases linearly across a wide age spectrum in CKD patients.

#3424
Shuo Zhang1, Xin Chen1, Zeoxian Hou3, Peng Xia1, Xiaoxiao Shi1, Wu Hai Ting1, Yu-Bing Wen1, Yan Qin1, Xinping Tian1 and Limeng Chen1
1Peking Union Medical College Hospital, Nephrology, Dongcheng-q, P.R. China and 2Peking Union Medical College Hospital, Rheumatology, Dongcheng-q, P.R. China

Background and Aims: Antineutrophil cytoplasmic autoantibody-associated vasculitis (AAV) is a type of necrotizing small vessel inflammatory disease, including alveolar hemorrhage and rapidly progressive glomerulonephritis. Elderly patients with antineutrophil cytoplasmic autoantibody-associated vasculitis (AAV) commonly experience renal impairment and poor prognosis. Based on the cohort of inpatients with AAV in Peking Union Medical College Hospital, this study aimed to analyze the clinical manifestations, diagnosis and treatment characteristics of elderly patients compared with non-elderly patients, and establish a risk scoring system for predicting composite renal outcomes in patients with AAV in elderly patients.

Method: This retrospective observational study included all AAV patients hospitalized in a single-center tertiary hospital in China between January 2013 and April 2022. Patients aged ≥ 65 years were defined as elderly and randomly divided into development and validation cohorts (2:1). Logistic regression analysis was performed in the development cohort to analyze risk factors. The scoring system was established accordingly and further validated in the validation cohort.

Results: A total of 1203 patients were enrolled in the study, among whom the elderly group accounted for 36% with a mean age of 71.4 ± 0.3 years. The elderly group had a worse prognosis, a higher mortality rate (8.9% vs. 3.5%, P < 0.001), a higher rate of end-stage renal disease (17.6% vs. 10.2%, P < 0.001), and worsening renal function (7.4% vs. 4.5%, P = 0.04). Logistic regression showed that age > 75 years, chronic heart disease, elevated serum creatine, and D-dimer values were risk factors for poor prognosis in patients with AAV. The development and validation cohorts in AAV patients produced area under the curve values of 0.823 (0.794–0.862) and 0.833 (0.777–0.888), respectively (Figure 1). When the risk score was ≥ 2 points, the risk of acquiring composite renal outcomes increased significantly with a sensitivity and specificity of 75.0% and 79.9%, respectively.

Conclusion: We established risk-scoring systems based on baseline clinical characteristics to predict composite renal outcomes in patients with AAV. Our results suggest that more attention should be paid to elderly patients who have severe renal impairment and active inflammation.

Figure 1: The scoring system for predicting composite renal outcomes and the receiver operating characteristic curve (ROC) in AAV patients.

PROTON PUMP INHIBITORS AND THE RISK OF ACUTE KIDNEY INJURY IN PATIENTS RECEIVING IMMUNE CHECKPOINT INHIBITORS: A POPULATION-BASED COHORT STUDY
Philip Vestergaard Munch1,2, Mette Norgaard1, Uffe Heide-Jørgensen1, Simon Kok Jensen1,2, Henrik Birn1,2 and Christian Fynbo Christiansen1,2
1Aarhus University Hospital, Department of Clinical Epidemiology, Aarhus N, Denmark, 2Aarhus University, Department of Clinical Medicine, Aarhus, Denmark, 3Aarhus University Hospital, Department of Renal Medicine, Aarhus N, Denmark and 4Aarhus University, Department of Clinical Medicine and Biomedicine, Aarhus, Denmark

Background and Aims: Proton pump inhibitors (PPI) are commonly used in cancer patients. Multiple studies have found that PPI use is associated with a more than 2-fold increased risk of acute kidney injury (AKI) in patients treated with immune checkpoint inhibitors (ICI). However, this association could possibly be explained by confounding by indication for PPI use.

Method: In a population-based cohort study, we compared the risk of AKI in users and non-users of PPI among cancer patients treated with ICI in Denmark during 2011-2021. We assessed exposure to PPI by filled prescriptions for PPI within 90 days before ICI initiation and identified AKI events within the first year after ICI initiation using plasma creatinine measurements from laboratory databases. We included information on potential confounders including important comorbidities and comedication. We estimated the propensity score for PPI use using logistic regression and calculated unweighted and standardized mortality ratio (SMR)-weighted absolute risks and hazard ratios (HRs) of AKI. To address any switch in PPI exposure during follow-up, we did an additional per-protocol analysis censoring patients upon switch in PPI exposure. We furthermore applied inverse probability of censoring (IPC) weights to mitigate informative censoring.

Results: We included 9,955 cancer patients treated with ICI. Among these, 2,668 (26.8%) were users of PPI. During the first year of follow-up, AKI occurred in 1,932 of the included patients, yielding an overall unweighted incidence rate of 30.1 per 100 person-years and a 1-year AKI risk of 21.3%. PPI users had an increased risk of AKI compared with non-users (1-year risk, 24.4% versus 20.2%; HR, 1.17 [95% CI, 1.04-1.31]); however, this association attenuated when accounting for confounders by SMR weighting (SMR-weighted 1-year risk, 24.0% versus 23.3%; SMR-weighted HR, 1.05 [95% CI, 0.93-1.18]). In the per-protocol analysis, the unweighted HR was 1.82 (95% CI, 1.60-2.07), while the SMR- and IPC-weighted HR was 1.22 (95% CI, 1.03-1.45).

Conclusion: PPI use at the time of ICI initiation was not associated with an increased risk of AKI after SMR weighting. When considering switching of PPI exposure during follow-up, we observed that PPI use was associated with an increased risk of AKI; however, the association was much weaker than previously reported.

#4489
EFFECT OF RENAL ARTERY CALCIFICATION ON THE OCCURRENCE OF ACUTE KIDNEY INJURY AND MORTALITY
Hae Eun Jeon1, Soie Kwon2 and Jin Ho Hwang1
1Chung-Ang University Hospital, Internal Medicine, Seoul, Rep. of South Korea and 2Seoul National University Hospital, Internal Medicine, Seoul, Rep. of South Korea

Background and Aims: Renal artery stenosis not only causes secondary hypertension and drug-resistant hypertension by enhancing renin-angiotensin-aldosterone system (RAAS), but also causes ischemic acute/chronic kidney injury by impeding blood flow to the kidneys. Renal artery calcification (RAC) suggests chronic severe ath erosclerotic changes, but the relationship between its severity and clinical prognosis has not been established.

Method: This study was conducted on subjects aged 60 years or older who had serum creatinine measured more than 3 times among patients prescribed and performed abdominal CT at Chung-Ang University Hospital from January 1, 2005 to February 28, 2020. The renal artery calcification score (RACS) was obtained by Agatston score measurement, and the incidence of AKI and mortality were compared between the groups.

Results: Of a total of 29,410 patients, 17,478 had no RAC and 11,932 was RAC (+). The median value of the group in which RACS was measured was 117.8. The prevalence and history of diabetes mellitus (DM), hypertension, dyslipidemia, and history of cardiovascular disease were significantly higher in the RAC (+) group, lower eGFR and higher proteinuria, and higher prescribing rates of ARB or ACEi, spironolactone, and statin. In the group of RAC (+), the incidence of AKI (HR 1.231, CI 1.174-1.292, P < 0.001, Figure 1) and all-cause mortality (HR 1.265, CI 1.182-1.355, P < 0.001) was high. Regardless of DM or RACS, the risk of AKI was higher in those who were prescribed ACEi or ARB
Figure 1: AKI-free survival by renal artery calcification.

(HR 1.786, CI 1.7-1.875, P < 0.001). In patients with DM, mortality risk was reduced in those taking ACEi or ARB regardless of the presence of RACS (HR 0.759, CI 0.645-0.892, P < 0.001).

**Conclusion:** RAC(+) was associated with higher AKI and mortality risk than RAC(-). The use of RAAS blockades increased the risk of AKI regardless of the presence of RAC, but reduced mortality in patients with DM regardless of the presence or absence of RACS.

**NEPHROTOXICITY OF CHIMERIC ANTIGEN RECEPTOR T CELL (CAR-T) THERAPY: ACUTE KIDNEY INJURY AND ELECTROLYTE DISORDERS**

Francesc Moncho Francés¹, Rafael Hernani Morales², Miguel Angel Solís², Ana Benzaquén Vallejos², Isabel Juan- García¹, Juan Carlos Hernández Boluda², Jose Luis Piñana Sanchez², Ariadna Pérez¹, Jose Luis Gorriz Teruel¹ and Isidro Antonio Torregrosa Maicas²

¹Hospital Clínico Universitario Valencia - INCLIVA, Nephrology, Valencia, Spain and ²Hospital Clínico Universitario Valencia - INCLIVA, Hematology, Valencia, Spain

**Background and Aims:** Chimeric antigen receptor T cell therapy (CAR-T) has improved the prognosis of patients with refractory hematologic malignancies. The most important toxicities are the cytokine release syndrome (CRS), where interleukin 6 (IL-6) plays a major role, and the immune effector cell-associated neurotoxicity syndrome (ICANS). A low incidence of acute kidney injury (AKI) with a high frequency of electrolyte imbalance has been described with CAR-T therapy. The aim of our study is to describe the nephrotoxicity of CAR-T therapy and to focus on AKI and the physiopathology of hypophosphatemia.

**Method:** A prospective single-center case series was performed which included all patients undergoing CAR-T therapy between 2020 and 2022. Clinical data included medical history, previous chemotherapy treatments, concomitant treatments, and clinical evolution. Daily monitoring of renal function, electrolytes and IL-6 was obtained after infusion of CAR-T. A urine sample was obtained on days 0, +7 and +14 with parathyroid hormone (PTH) and 25-OH vitamin D. AKI was classified according to the KDIGO criteria.

**Results:** 40 patients received CAR-T therapy during the follow-up period. The median age was 62 years. The same number of men as women were included. The most frequent comorbidities were hypertension (27.5%), followed by diabetes (12.5%) and chronic kidney disease (12.5%). 12 patients presented AKI. Baseline serum creatinine (SCr) in patients with AKI was 0.9 mg/dL (0.68-1.04) with a SCr peak of 1.27 mg/dL (1.1-1.7). The time from CAR-T therapy infusion to SCr peak was 6.5 days (4-10). Of these 12 patients, 8 presented stage 1, 3 stage 2, and 1 stage 3 AKI. There were no differences between the AKI and non-AKI group in baseline characteristics, inflammatory markers, CRS, ICANS or hospital length stay. Hypophosphatemia was the most frequent electrolyte imbalance, occurring in 36 patients (90 %), 22 (61 %) patients experienced moderate hypophosphatemia (phosphorus < 2 mg/dL) while 14 (39 %) patients experienced mild hypophosphatemia. 29 patients (72 %) presented hypokalemia and 25 patients (62.5 %) hyponatremia. Patients with moderate hypophosphatemia had a significantly higher elevation of IL-6 but there were no differences in PTH or vitamin D (Table 1). Although there were no significant differences in fractional excretion of filtered phosphate (FEPO4), patients with moderate hypophosphatemia trend to have higher FEPO4 values.

**Conclusion:** Electrolyte disturbances are common in CAR-T therapy, with hypophosphatemia being the most frequent. There is probably a mechanism for renal phosphorus loss related to systemic inflammation. AKI is less frequent and has mild characteristics in these patients.

**ECOLOGICAL APPROACH FOR KIDNEY REPLACEMENT THERAPY IN CRITICAL CARE: SLED MAY BE A STRATEGY**

Inês Sala¹, Ana Carlota Vida¹, Liliana Lopes¹, João Fernandes¹, Anselmo Madureira¹, Ana Castro¹, Cristina Ferreira¹ and Luísa Lobato¹

¹Hospital de Santo António (HSA), Centro Hospitalar Universitário do Porto (CHUPorto), Porto, Portugal. Department of Nephrology, Portugal and ²Hospital Central do Funchal, Funchal, Madeira, Portugal. Department of Nephrology, Portugal

**Background and Aims:** Dialysis has an enormous environmental impact, not only for disposable consumables, but also for the water and energy consumption. Despite increasingly evidence regarding comparable outcomes between continuous kidney replacement therapy (CKRT) and slow low efficiency dialysis (SLED), ecological-based endpoints are not frequently evaluated. Literature in critical care concerning the environmental impact of these techniques is scarce. We aimed to determine the waste production, water and energy consumption in SLED and CKRT and identify the technique with higher environmental impact.

**Method:** We conducted a cross-sectional, observational, single-center study in patients with acute kidney injury requiring kidney replacement therapy admitted to an intensive care unit (ICU). We analyzed the waste weight of each dialysis technique (Fresenius Medical Care 5008 for SLED and Baxter Prismaflex for CKRT) before and after the treatment. We estimated the unpurified water consume of 8-hours and 12-hours SLED treatment was 237 L and 345 L, respectively. For CKRT, we estimated a consume of 43.2 L a day and 129.6 L for a 72-hour treatment. SLED had an energy consumption of 5.71 kW and 8.43 kW, for 8-hours and 12 hours treatment, respectively. The CKRT consumed about 12 to 14.4 kW per day.

**Results:** A SLED session produced 1600 g of waste (1200 g was hazardous and 400 g was non-hazardous waste). A CKRT session produced 2700 g of waste, not considering the substitution solution volume, which can vary up to a maximum of 15000 g/treatment. Waste consumables for each technique are discriminated in Table 1. The unpurified water consume of 8-hours and 12-hours SLED treatment was 237 L and 345 L, respectively. For CKRT, we estimated a consume of 43.2 L a day and 129.6 L for a 72-hour treatment. SLED had an energy consumption of 5.71 kW and 8.43 kW, for 8-hours and 12 hours treatment, respectively. The CKRT consumed about 12 to 14.4 kW per day.

**Conclusion:** Our study highlights the quantity of waste produced, water and power consumption of dialysis techniques in the critical patient. CKRT produces more hazardous waste, that generates a larger carbon footprint. Hazardous waste cannot be recyclable and implies specific management and disposal, which is more expensive and laborious than non-hazardous. CKRT has also a higher power consumption due to treatment duration and technology used to generate electricity. SLED has higher water consumption, nevertheless, current strategies used in hemodialysis units could also be implemented in ICU to minimize this effect. For example, the rejected water can be reused to agriculture and toilet flushing; more efficient water purification system with a lower proportion of rejected water can also reduce water consumption. SLED has unequivocal clinical benefits in the critical patient and, from an ecological perspective, seems to be a more sustainable option.
Background and Aims: Haemolytic uraemic syndrome (HUS) is a disease which affects the kidneys presenting with acute kidney injury (AKI), microangiopathic haemolytic anaemia (MAHA) and thrombocytopenia. In 90% of cases it is precipitated by shiga-toxin producing E coli [1]. The remaining 10% of cases have been termed atypical haemolytic uraemic syndrome (aHUS) and complement system overactivation is the underlying mechanism [2]. This can take the form of autoantibody production or complement gene mutations [2]. Eculizumab has been proven to significantly ameliorate disease progression [3]. In this series, we sought to explore the West of Scotland’s experience with this ultra-rare population evaluating outcomes and access to therapies.

Method: This is a retrospective case series. We extracted data from the west of Scotland renal electronic patient records database Strathclyde Electronic Renal Patient Record (“SERPR”) provided by VitalDataClient. We ran a query to identify patients in whom TMA and/or MAHA and/or HUS was inputted as a diagnosis. 363 patients were identified. Filtering for aHUS in the adult population, 22 patients were identified spanning 19 years.

Results: The incidence rate is 0.43/million of the population. 14 patients had either genetic mutations (n=13) or acquired antibodies. Genetic mutations: C3, n=5; Complement Factor H (CFH) n=5; Complement Factor I (CFI) + CD46 n=1; CFI alone n=1, variants of uncertain significance n=1. One patient with CFH mutation was positive for the nephritic factor; another with CFH mutation had detectable Factor H autoantibodies. The only acquired patient without a genetic mutation had Factor H autoantibodies. The mean levels of biochemical markers at presentation are: Haemoglobin (g/L) 72; Creatinine, (μmol/L) 603; Platelet count, (×10⁹/L) 89; Lactate dehydrogenase (IU/L) 1853; and Total Bilirubin, (μmol/L) 90. Eculizumab is an available treatment for aHUS utilised in coordination with The National Renal Complement Therapeutics Centre. The outcomes of patients with and without genetic defects and/or antibodies, with the number in parenthesis denoting those who received Eculizumab, are listed below, stratified by CKD staging. Those with identifiable genetic/acquired defects: Recovered 2(2); CKD3 3(3); CKD4 1(0); Renal replacement therapy dependent 7(6)*. Total 14(11). Those with no identifiable defect: Recovered 2(2); CKD3 2(0); CKD4 0; Renal replacement therapy dependent 4(3)**. Total 8(5). *4 of the 6 have successfully functioning transplants. **Of the 3 patients who received Eculizumab, 2 had a brief trial. The third received it after transplantation but the transplant failed.

Conclusion: It is clear from the above data that long term renal outcomes are poor for these patients with the majority being left with residual impairment to some degree. Furthermore, in those for whom transplantation is being considering, it is imperative that Eculizumab is introduced, if already withdrawn, to cover transplantation and is maintained to prevent recurrence in the new organ. Even in those without RRT requirements, use of the C5 inhibitor is necessary to stabilise and allow for recovery of at least some native function. Therefore, clinicians in encountering MAHA and TMA in their practice should always consider aHUS and liaise with the Newcastle centre promptly to ensure diagnostics are sent and treatment can be commenced, otherwise the outcomes can be catastrophic.

REFERENCES
Results: Of the 29,635 patients administered iodine-based contrast media, 6.3% were included. There were 139 patients who mix-administered iodine-based contrast media and GBCA. Mixed group showed significant higher rate of development of PC-AKI compared with iodine-based contrast media alone group in total cohort (adjusted OR, 3.09 [95% CI, 2.09 – 4.58]) and PSM cohort (adjusted OR, 2.38 [95% CI, 1.25 – 4.55]). On multivariate analysis to investigate risk factors in Mixed group, osmolality (adjusted aOR, 1.05 [95% CI, 1.01–1.10]) and eGFR (adjusted OR, 0.931; 95% CI, 0.883–0.983) were associated with PC-AKI.

Conclusion: Mixed administration of iodine-based contrast media and GBCA on same day at ED visit may be a risk factor for PC-AKI compared with single administration of iodine-based contrast media alone. Osmolality and eGFR may be independently associated with PC-AKI after mixed administration of iodine-based contrast media and GBCA.

FLUID BALANCE AND GLOMERULAR FILTRATION RATE AS PREDICTORS OF OUTCOME AMONG COVID-19 PATIENTS IN THE ICU

Anes Jogunčić1, Petar Djuric2, Anisa Gradaščević1, Christina Torka1, Mark Rosenberg3, Ognjen Gajić4 and Stefan Büttner1

1Public Health Institute of Canton Sarajevo, Bosnia and Herzegovina, Epidemiology, Sarajevo, Bosnia and Herzegovina, 2Zvezdara University Medical Center, Department of Nephrology, Belgrade, Serbia, 3Klinikum Aschaffenburg-Alzenau, Intensiv care Unit, Pulmonology, Kardiology and Nephrology, Aschaffenburg, Germany and 4Mayo Clinic Pulmonary Medicine, Division of Pulmonary and Critical Care Medicine, Rochester, United States of America

Background and Aims: Acute kidney injury (AKI) is associated with an increased risk of progression to a severe form in every disease and, moreover, is associated with an increased mortality, and so it is also with coronavirus disease 2019 (COVID-19). AKI is a frequent complication in COVID-19 patients admitted to ICU for severe respiratory failure. ICU treatment itself indirectly could cause or exacerbate renal damage, through suboptimal fluid management, drug toxicity, or low human resources. The aims of this study were to assess AKI prevalence, fluid balance and glomerular filtration rate as a predictor of outcome in COVID-19 patients treated in the intensive care unit.

Method: We retrospectively analysed all adult patients admitted to the ICU at a regional hospital in northern Bavaria, from 1st March to 31st December 2020. Clinical data and laboratory results were retrospectively retrieved from the hospital information system and electronic case files. According to the severity of AKI based on the KDIGO criteria, and laboratory values were followed on the first 7 days on the ICU. In total 320 patients patients were included in the study. Level of significance was set to p<0.05.

Results: The mean age was 65±19 years, 135 (42%) patients were females, 185 (58%) were males. Median length of ICU stay was 7 (2–13 days) in females, and 8 days (4–21 days) in males. At the ICU, 177 patients needed some form of ventilation, from which 109 needed Invasive mechanical ventilation). During ICU stay, 81 patients have died, with mortality rate of 25%. Patients with AKI (n=48, 15%) at the admission to the ICU, had 2.1 times higher risk of death at the ICU than patients without AKI. There was a statistically significant difference in ICU survival based on a glomerular filtration rate, fluid balance, CRP and leukocyte values, F=1.957, p=0.026; Wilk’s Λ=0.724, partial η2 = 0.276

Conclusion: Acute kidney injury is common in coronavirus disease 2019, and it is associated with poor clinical outcomes. Even first couple of days at the ICU could point to the outcome, with markers of inflammation, glomerular filtration rate, and fluid balance being most valuable variables.
among children. Such information is important for AKI prevention, resource allocation, and future research. In this study, we aimed to examine overall temporal changes in the rate of hospital- and community-acquired pediatric AKI and to describe associated changes in potential underlying risk markers.

**Method:** In this population-based cohort study, we included children aged 0-17 years from 1 January 2007 to 31 December 2021 in Denmark. In 2021, the Danish population consisted of 1,168,222 children. We obtained clinical plasma creatinine measurements from the Danish laboratory databases to identify all KDIGO-defined AKI episodes within the study period. For each child, only the first AKI episode per year was included and we defined an AKI episode as a period of 30 days. AKI was defined as community-acquired if the plasma creatinine at time of AKI was taken in the outpatient clinic or the first day of admission/acute setting. We estimated the annual AKI rate for first AKI episodes in a year among children residing in an area covered by the laboratory databases divided by the number of children residing in this area in the same year. Unadjusted rates as well as sex- and age-standardized rates was reported. Using Danish medical databases, we identified potential risk markers for AKI, such as use of nephrotoxic medication, surgery, sepsis, and perinatal factors including low birth weight and preterm birth.

**Results:** In total, 14,262 children contributed with 16,492 AKI episodes. The average annual rate of AKI was 149 per 100,000 children and was stable throughout the study period (figure). Of the AKI episodes, 10,921 (66.2%) were community-acquired and 12,714 (77.1%) were stage 1 AKI. No major changes were seen in the prevalence of risk makers among AKI episodes.

**Conclusion:** The rate of AKI among Danish children was stable from year 2007 to 2021 and potential risk markers were largely similar over time.

**DYNAMIC EFFECT OF PROTEINURIA ON ADVERSE KIDNEY OUTCOMES WITH TARGETED MAXIMUM LIKELIHOOD ESTIMATION METHOD: RESULT FROM THE KNOW-CKD STUDY**

Yun Jung Oh1, Kook-Hwan Oh2, Wookyung Chung3 and Ji Yong Jung4

1H+ Yangi Hospital, Nephrology Department of Internal Medicine, Seoul, Rep. of South Korea, 2Seoul National University College of Medicine, Nephrology Department of Internal Medicine, Seoul, Rep. of South Korea and 3Gachon University Gil Medical Center, Nephrology Department of Internal Medicine, Incheon, Rep. of South Korea

**Background and Aims:** Proteinuria is a risk factor for the progression of chronic kidney disease (CKD), but its causal inference may be challenging due to time varying exposure and confounding, the changing its degree, and loss to follow up.

**Method:** A total of 1,223 patients enrolled as part of The Korean Cohort Study for Outcome in Patients With Chronic Kidney Disease (KNOW-CKD) were analyzed at 3 observational points (baseline, 3-year, early, and 7-year, late) at which spot urine protein creatinine ratio (UPCR) was measured. We used longitudinal targeted minimum loss-based estimation (TMLE) and marginal structural models (MSM) to estimate the cumulative incidence of adverse kidney outcomes (eGFR halving and kidney failure requiring replacement therapy) of dynamic exposure to high proteinuria (UPCR ≥1g/g) comparing counterfactuals (UPCR <1g/g) adjusted for time varying confounding (systolic blood pressure, estimated glomerular filtration rate, and renin-angiotensin-aldosterone blockers) and baseline covariates (age, sex, diabetes, cardiovascular disease, and smoking).

**Results:** Patients with sustained high proteinuria throughout 7-year follow-up had significant higher risk of renal events than those with counterfactuals (relative risk [RR], 3.120; 95% confidence interval, 2.150-4.528; P < 0.001). The RR were 0.168 (0.055-0.517; P = 0.002) and 0.613 (0.337-1.114; P = 0.108) for early and late proteinuria reduction comparing sustained high proteinuria, respectively. In MSM, hazard ratio (HR) of accumulative high proteinuria frequency were 1.612 (1.463-1.844; P < 0.001) up to 3 years and 1.102 (0.877-1.387; P = 0.404) up to 7 years, respectively.

**Conclusion:** In CKD patients, sustained higher proteinuria is the main risk factor during the entire observation period. However, considering dynamic exposure, proteinuria reduction from the beginning has a protective effect on renal progression, but the effect weakens as the observation period becomes longer.
BP, background CV comorbidities, anti-hypertensive drugs, haemoglobin, albumin, phosphate, hs-CRP, 24h proteinuria, and eGFR, the hazard rate (HR) of renal events decreased in a dose-dependent fashion from the lowest bicarbonate trajectory (reference category, HR 1) to the moderate (HR:0.70, 95%CI 0.43-1.14), high moderate (HR:0.54, 95%CI 0.31-0.93), and high bicarbonate category (HR:0.31, 95%CI 0.12-0.80) (P for trend=0.005). Thus, for patients in the high bicarbonate category (27.9± 2.8 mEq/L), there is an 69% risk reduction for renal composite endpoint.

Conclusion: In a longitudinal analysis of a cohort of CKD patients, high bicarbonate levels are associated with a substantially reduced risk of renal events. These findings represent a strong call for well-designed, adequately powered randomised trials testing the effect of bicarbonate supplements or pharmacologic interventions that increase serum bicarbonate on renal outcomes. Given the substantial risk reduction in patients in the highest bicarbonate trajectory, these trials are an absolute clinical research priority.

THE EFFECT OF COVID-19 WITH OR WITHOUT ACUTE KIDNEY INJURY ON INPATIENT MORTALITY IN ENGLAND

Nitin Kolhe1, Richard Fluck1 and Maarten Taal1,2

1University Hospitals of Derby and Burton, Renal Medicine, Derby, United Kingdom and 2University of Nottingham - Derby campus, Department of Medicine, Derby, United Kingdom

Background and Aims: COVID-19 and acute kidney injury (AKI) are each associated with increased mortality but the interaction between these two conditions has not been adequately investigated with appropriate control groups. The aim of this national study was to assess patient characteristics and mortality and well as associations with higher mortality in patients with or without COVID and with or without AKI.

Method: We extracted 3,324,748 finished consultant episodes (FCE) of all adult patients admitted patients between March 20 and March 21 from England’s national database of all hospitals. We excluded patients on chronic dialysis, acute dialysis in CKD, acute dialysis with no AKI codes or not residing in England. We also excluded multiple FCEs within same spell and duplicate FCEs. We divided the study period in two phases of SARS CoV-2 strains. "Other" strain of SAR CoV-2 was dominant between 1st March 2020 and 21st December 2020 and "Alfa" strain was dominant between 22nd December 2020 to 17th May 2021. The end date of each phase was based on more than 50% decline in each variant. We further categorised phases based on publication of the RECOVERY trial.

Results: There were 663,628 patients with 2,385,337 admissions out which 856,544 had AKI as identified by N17 codes while 1,528,793 had no AKI. There were 1,008,774 admissions in 133,988 patients who did not have AKI or COVID (group 1) and 520,019 admissions in 256,037 patients who had COVID (group 2). Amongst admission with AKI, there were 630,342 admissions in 218,270 patients who did not have COVID-19 (group 3) and 226,202 admissions with COVID in 55,333 patients (group 4). Patients in group 4 were older (75.4 ± 13.8 years) and had greater length of stay (17.1 ± 17 days) than all other groups. Acute dialysis was performed in 1.4% of patients in group 3 and 3.6% of patients in group 4. Crude in-hospital mortality was highest in group 4 at 28.7% and lowest in group 1 (1.1%). Critical care requirement was lowest in group 1 (1.2%) compared to group 4 (10.9%) as was ITU mortality (4.8% versus 47.8%). In multivariable analysis, when compared with group 1, patients in group 4 had highest odds of death (OR 22.28, 95%CI 21.79, 22.78) followed...
by patients with group 2 (OR 9.67, 95%CI 9.46-9.88) (Figure 1). Patients in group 3 had OR of 6.44, 95%CI 6.30-6.58. Odds of death were lower during post-RECOVERY phase with "Other" (OR 0.80, 95%CI 0.79, 0.81) and "Alfa" (OR 0.86, 95%CI 0.85, 0.87) SARS-CoV-2 strains (Figure 2).

**Conclusion:** This national study shows that the COVID pandemic had great impact on mortality in England and the odds of death increased substantially when complicated by AKI. Moreover, AKI associated with COVID was associated with a substantially higher odds of death than AKI due to other causes. The change in practice after publication of the RECOVERY trial was associated with a lower odds of death.

#3372

**HOST RESPONSE CHANGES ASSOCIATED WITH PERSISTENT ACUTE KIDNEY INJURY IN CRITICALLY ILL PATIENTS WITH COVID-19**

H Peters-Sengers,1,2 Koen de Kruif,1 Thee Steenvoorden,1 Brent Appelman1, Renée Douma3, Lieuwe Bos3, Tom van der Poll1,4, Joost Wiersinga,1,3 and Lifert Vogt1

1 Amsterdam UMC, Location University of Amsterdam, CEMM (Center for Experimental and Molecular Medicine), Amsterdam, Netherlands, 2 Amsterdam UMC, Location University of Amsterdam, Department of Clinical Epidemiology, Biostatistics and Bioinformatics, Amsterdam, Netherlands, 3 Amsterdam UMC, Location University of Amsterdam, Department of Nephrology, Amsterdam, Netherlands, 4 Flevo Hospital, Internal Medicine, Almere, Netherlands, 5 Amsterdam UMC, Location University of Amsterdam, Department of Intensive Care Medicine, Amsterdam, Netherlands, 6 Amsterdam UMC, Division of Infectious Diseases, Amsterdam, Netherlands and 7 Amsterdam UMC, Location University of Amsterdam, Division of Infectious Diseases, Amsterdam, Netherlands

**Background and Aims:** In sepsis, the dysregulated host response has been, at least in part, linked to development of acute kidney injury (AKI) and its duration. Data on the host response to COVID-19 and development of persistent-AKI (duration > 48 h) in critically ill patients are scarce. We hypothesized that COVID-19 infected patients who develop persistent-AKI have different host response aberrations. To address this hypothesis, we sequentially measured host immune response biomarkers in critically ill patients admitted to the intensive care unit (ICU).

**Method:** We included patients admitted to the ICU from two tertiary hospitals and one primary care hospital between March and July 2020 (first wave). All patients had PCR-confirmed COVID-19. Excluded were readmitted patients, transfers from another ICU, and patients with chronic kidney disease (CKD stage 3 or higher). The presence of AKI was assessed by using hourly urine output and daily serum creatinine levels, and classified into 3 stages according to Kidney Disease: Improving Global Outcomes (KDIGO) criteria. In a subset of patients admitted to the two tertiary hospitals (n=113), 41 plasma protein biomarkers were sequentially measured using a Luminex platform or ELISA, and categorized into five pathophysiological domains: systemic inflammation, endothelial cell activation and dysfunction, coagulation activation, kidney dysfunction, and lung dysfunction. Mixed effects models were used to analyse longitudinal data.

**Results:** Of 185 ICU admissions enrolled, 8 were excluded because of existing CKD. Of the remaining 177 patients, 106 patients (59.9%) had AKI within the first 48 h of admission; of these, 76 patients (71.7%) had persistent AKI and 30 patients (28.3%) transient AKI. Patients with persistent AKI more often were obese and had a history of hypertension. A higher disease severity – as determined by the sequential organ failure assessment (SOFA) score - was observed in the persistent AKI group, which was driven by the renal component as the non-renal SOFA score was similar between no-AKI, transient- and persistent AKI. Sequential protein biomarker analyses revealed that five biomarkers were significantly elevated in persistent-AKI compared to transient-AKI in the first four days, mainly related to inflammation (triggering receptor expressed on myeloid cells-1 [TREM-1], p=0.003; tumour necrosis factor receptor 1 [TNF-R1], p < 0.001; lung dysfunction (clara cell secretory protein [CC16], p < 0.001), and kidney dysfunction (Cystatin C [p < 0.001]; neutrophil gelatinase-associated lipocalin [NGAL], p < 0.001). Plasma protein biomarkers reflective of endothelial cell- and coagulation activation were not different in patients with persistent-AKI as compared to patients with transient-AKI. No differences in plasma biomarkers were observed between transient AKI and no-AKI.

**Conclusion:** Transient AKI and no-AKI revealed little to no differences, while the persistent AKI group demonstrated stronger host response anomalies across the pathophysiological domains of inflammation and lung dysfunction. In contrast to what has been observed in non-COVID-19-related sepsis, endothelial injury and coagulation activation markers were not associated with AKI trajectories. These findings suggest that COVID-19 can induce a robust immune response that contributes to persistence of AKI, largely mediated through inflammatory responses.

#3534

**ASSOCIATION OF STOPPING RENIN-ANGIOTENSIN SYSTEM INHIBITORS DURING AN ACUTE KIDNEY INJURY EPISODE WITH CARDIOVASCULAR AND ALL-CAUSE MORTALITY**

Yanqin Li, Sheng Nie, Xu Xin and Fan Fan Hou

National Clinical Research Center for Kidney Disease, State Key Laboratory of Organ Failure Research, Nanfang Hospital, Southern Medical University, Division of Nephrology, Guangzhou, P.R. China

**Background and Aims:** The management of angiotensin-converting enzyme inhibitor (ACEI) and angiotensin receptor blocker (ARB) in patients with ongoing acute kidney injury (AKI) during hospitalization is debated. This study is aimed to explore whether the use of ACEI or ARB (ACEI/ARB) during an AKI episode is associated with adverse clinical outcomes.

**Method:** This nationwide, retrospective cohort study included 10,559 patients aged 18–100 years who had a hospital-acquired AKI (HA-AKI) episode and who were using ACEI/ARB at the time of AKI detection during the hospitalization between January 1, 2000 and May 26, 2021 from 19 medical centers across China. The primary exposure was stopping or continuing the use of ACEI/ARB after HA-AKI detection during hospitalization. The primary outcome was all-cause mortality (30-day, 180-day, and in-hospital mortality) after HA-AKI. Secondary outcomes included cardiovascular death and new-onset chronic kidney disease (CKD). Propensity scores were used to construct a matched-pairs cohort of patients who stopped or continued the use of ACEI/ARB during the HA-AKI episode.

**Results:** This study included 10,559 adults (mean [standard deviation] age, 67.4 [14.4] years; 6,606 [62.6%] male). A total of 2,015 (19.1%) participants stopped the usage of ACEI/ARB within 1 day after AKI detection. Among 1,915 matched-pairs, compared with those continued the use of ACEI/ARB, stopping the use of ACEI/ARB was associated with lower risks of 30-day all-cause mortality (adjusted hazard ratio (aHR), 0.67; 95% confidence interval [CI], 0.51-0.87), 180 day all-cause mortality (aHR, 0.77; 95%CI, 0.63-0.94) and in-hospital all-cause mortality (aHR, 0.64; 95%CI, 0.46-0.87). Similar results were found between stopping the use of ACEI/ARB and the risks of 30-day cardiovascular death (aHR, 0.58; 95%CI, 0.49-0.69), 180-day cardiovascular death (aHR, 0.57; 95%CI, 0.36-0.80), in-hospital cardiovascular death (aHR, 0.41; 95%CI, 0.19-0.86), and new-onset CKD after discharge (aHR, 0.76; 95%CI, 0.61-0.96). These protective effects were consistent in multiple sensitivity analyses.

**Conclusion:** Our study for the first time demonstrates that stopping the use of ACEI/ARB during an AKI episode is associated with lower risks of mortality and new-onset CKD. These findings provide strong evidence for the recommendation of avoiding renin-angiotensin system inhibitors during AKI from clinical guidelines.
**INCIDENCE, OUTCOMES AND RISK FACTORS OF ACUTE KIDNEY INJURY IN PATIENTS THAT UNDERWENT TRANSCATHETER AORTIC VALVE REPLACEMENT**

Suramath Isaranuwatchai, Wutipong Triwatana, Amaraluk Jitpreeda, Netnaps Sri rattana and Damrong Sukitpunyaroj

Chulabhorn Hospital, Internal Medicine, Bangkok, Thailand

**Background and Aims:** The incidence of acute kidney injury (AKI) in transcatheter aortic valve replacement (TAVR) varied among different centers and populations. The studies about the AKI in TAVR in Asian population were relatively scarce. Here, we reported the first descriptive study of AKI in patients underwent TAVR in Thailand. We also analyzed the risk factors of AKI in patients underwent TAVR.

**Method:** We reviewed the medical records of patients underwent TAVR in Chulabhorn hospital from August 2019 to September 2022. Baseline characteristics, serum creatinine and estimated glomerular filtration rate (eGFR) at baseline, day 2, day 7 and at discharge were recorded. Patients who did not have serum creatinine measured at day 2 or day 7 were excluded from our study. Patients who already underwent hemodialysis or peritoneal dialysis before TAVR also excluded from our study. We used the definition of AKI by KDIGO guideline. Outcome of AKI including 30-day mortality, 1-year mortality and renal replacement therapy were also recorded.

**Results:** We included 113 patients who underwent TAVR, all of which had the diagnosis of severe symptomatic aortic stenosis. 56 patients (49.6%) were male patients. The mean age was 80.2 +/- 5.6 years. The average length of stay was 9.9 days. 54 patients (47.8%) had pre-existing chronic kidney disease (CKD) before underwent TAVR. Other co-morbidities were hypertension (81/113 = 71.7%), dyslipidemia (71/113 = 62.8%), prior myocardial infarction (53/113 = 46.9%), diabetes (36/113 = 31.9%), and prior stroke or transient ischemic attack (5/113 = 4.4%). AKI occurred in seven patients (6.2%). Four patients (4/7 = 57.1%) underwent acute dialysis after TAVR. 30-day mortality rate was 0% and 1-year mortality rate was 1.8%. The 1-year mortality rate in patient with AKI was 14.3% compared with 0% in patient without AKI. The univariate analysis revealed that age, prior myocardial infarction, pre-existing CKD and pre-TAVR serum creatine were risk factors for developing AKI after TAVR.

**Conclusion:** This is the first study exploring incidence, outcomes and risk factors of AKI in patients underwent TAVR in Thailand. The incidence of AKI was 6.2%, relatively low compared with previous study.

**USEFULNESS OF CYSTATIN C IN MEASURING RENAL FUNCTION AND PREDICTING METHOTREXATE ASSOCIATED TOXICITIES IN PATIENTS WITH RHEUMATOID ARTHRITIS**

So Mi Kim¹, Eun Kyong Lee², Ji Hyun Jeon³, Jong Tae Cho³ and Hwa Young Lee⁴

¹Dankook University Hospital, Division of Nephrology, Department of Internal Medicine, Rep. of South Korea, ²Dankook University Hospital, Division of Nephrology, Rep. of South Korea, ³Dankook University Hospital, Rep. of South Korea and ⁴Jeju National University Hospital, Rep. of South Korea

**Background and Aims:** Rheumatoid arthritis (RA) is a representative chronic disease accompanied by muscle loss, and cystatin C may be more useful than traditional creatinine (Cr) when measuring renal function. RA is affected not only by drug dose but also by side effects of treatment according to renal function. Therefore, we tried to compare the estimated glomerular filtrate rate (eGFR) using cystatin C and Cr and analyze the methotrexate (MTX) associated toxicities after treatment.

**Method:** A total of 436 RA patients was enrolled in this study. The eGFR was calculated using the Chronic kidney Disease Epidemiology Collaboration (CKD-EPI) equation based on cystatin C and serum Cr. According to eGFR, CKD stages and drug dosing stages were classified and MTX associated toxicities were evaluated.

**Results:** Mean eGFR using the CKD-EPI Cr and CKD-EPI cystatin C equations were 95.36 and 89.44 mL/min. In the CKD-EPI Cr group, there were 11 patients with eGFR less than 50 mL/min that required dosing reduction, and 38 patients in the CKD-EPI cystatin C group. According to eGFR, CKD stages and drug dosing stages were classified and MTX associated toxicities were evaluated.

**Conclusion:** Mean eGFR using the CKD-EPI Cr and CKD-EPI cystatin C equations were 95.36 and 89.44 mL/min. In the CKD-EPI Cr group, there were 11 patients with eGFR less than 50 mL/min that required dosing reduction, and 38 patients in the CKD-EPI cystatin C group, showing a statistically significant difference (Table 1A). In addition, CKD stage 3B and 4 patients were also higher in the CKD-EPI cystatin C group compared to those in CKD-EPI Cr group (Table 1B), and anemia and nephrotoxicity were high in the MTX related toxicity stage upgraded group.
Conclusion Our study showed that eGFR by CKD-EPI C2 can be overestimated than that by CKD-EPI Cystatin C, and also demonstrated higher MTX associated toxicities in the group, which the stage was changed upward. Therefore, this study suggests that cystatin C is a useful predictor in measuring renal function and predicting MTX associated toxicities in RA patients

PROGRESSION TO END-STAGE RENAL DISEASE AND ONE-YEAR MORTALITY IN ACUTE CARDIORENAL SYNDROME
Maria Muñiz Rincón, Jesús Domínguez Delgado-Palacios, Arianné Aiffil Meneses, Marta Calvo Arevalo, Juez Del Pozo Almudena, Sara Huertas Salazar, Rómulo Katsu Loayza López, Clara García Carro, Natividad Calvo Romero, Elena Ruiz Ferreras and Ana Sanchez Fructuoso

Hospital Clínico Universitario San Carlos, Nephrology, Madrid, Spain

Background and Aims: Approximately 25% of patients with chronic congestive heart failure (CHF) present a reduction in glomerular filtration rate (GFR) independent of the left ventricular ejection fraction (LVEF). A meta-analysis of 80,000 patients revealed that patients with lower GFR (<53 mL/min) had a higher one-year mortality rate (51% versus 38%). Therefore, this reduction in GFR seems to have an important impact on both morbidity and mortality. The aim of this study was to analyze the factors associated with progression to advanced chronic kidney disease (CKD) and one-year mortality in a retrospective cohort of patients hospitalized due to acute decompensation of cardiorenal syndrome (CRS).

Method: Patients hospitalized for CRS between September 2013 and June 2020 who presented acute kidney injury (AKI) associated with CHF. Clinical, meta-analysis of 80,000 patients revealed that patients with lower GFR (<53 mL/min) had a higher one-year mortality rate (51% versus 38%). Therefore, this reduction in GFR seems to have an important impact on both morbidity and mortality. The aim of this study was to analyze the factors associated with progression to advanced chronic kidney disease (CKD) and one-year mortality in a retrospective cohort of patients hospitalized due to acute decompensation of cardiorenal syndrome (CRS).

Results: The study included 100 patients with a majority of males (64%) and a median age of 79.5 years (72.3–85.0). Around 38% of the patients were dependent, 49% had ischemic heart disease, 51% were diabetic, 27% had left ventricular hypertrophy, 56% had moderate to severe pulmonary hypertension, and 59% had moderate to severe valve disease. In terms of LVEF, 27% showed severe dysfunction while 42% had preserved function. The median baseline creatinine was 1.6 mg/dl (1.3–2.0) with an estimated glomerular filtration rate (eGFR) of 36 mL/min (29.0–46.5). At the time of acute renal failure (ARF), creatinine was 3.3 mg/dl (2.8–4.0) and at hospital discharge the eGFR (CKD-EPI) was 29.5 mL/min (20.1–40.0). After one year of follow-up, 49 patients had died, 7 were admitted for chronic hemodialysis, and 6 showed a drop in eGFR greater than 40%. A logistic regression analysis was conducted for the outcome variable of "death or severe progression of CKD (considering entry into CKD grade V or loss of more than 40% of GFR)". Hyperphosphatemia (76% death/progression vs 48%, p=0.004), discharge eGFR less than 30 mL/min (74% vs 50%, p=0.013), and renin-angiotensin system (RAS) blockade (48.1% vs 77.1%) were significantly associated with the outcome. Systolic dysfunction was associated with 70.4% of death/progression (52.2% p=0.06).

In the multivariate analysis, variables with a trend in the univariate analysis (p<0.2), such as prolonged hospital stay, non-revascularized coronary disease, hyponatremia, and proteinuria, were included. The analysis showed that five variables were significantly associated with the risk of death/CKD progression: proteinuria (OR 2.8, 95% CI 1.03-7.37, p=0.04), discharge eGFR (OR 2.7, 95% CI 1.05-6.82, p=0.04), LVEF (OR 0.97, 95% CI 0.94-1.00, p=0.06), hyponatremia (OR 0.89, 95% CI 0.80-0.99, p=0.04), and RAS blockade (OR 0.19, 95% CI 0.07-0.53, p=0.001). The predictive model had an area under the curve of 0.79 (95% CI 0.70-0.88) with a p-value of 0.047 and a global accuracy of 77%.

Conclusion: In conclusion, our study found that hyponatremia and proteinuria were significantly associated with a poorer outcome in terms of CKD progression and mortality in patients with cardiorenal syndrome. Conversely, higher left ventricular ejection fraction and a higher estimated glomerular filtration rate at discharge from the decompensation episode were linked to a lower risk. Our findings support the use of RAS-blocking drugs as beneficial in this population.

#6448
IMPACT OF PRE-DIALYSIS FOLLOW-UP ON OUTCOMES IN DIALYSIS PATIENTS
Adrian Guinsburg, Maria Inés Díaz Bessone and Mauro Caseiro

Fresenius Medical Care, Argentina

Background and Aims: Pre-dialysis care aims to slow down the decline in kidney function and to prepare patients for their potential start of renal replacement therapy. Patients who received attention earlier showed reduced mortality and hospitalization, better uptake of peritoneal dialysis, and earlier placement of arteriovenous fistula for hemodialysis. The objective of this study is to analyze the impact of pre-dialysis care in dialysis patients from Fresenius Medical Care Latin America (FMEA).LAtrAm).

Method: Patients incident to dialysis that started treatment at FME LatAm between January 2019 and December 2022 were included in this retrospective observational study. They were classified according to whether they received pre-dialysis care or not as CKD (more than 10 days of follow up) or No CKD (less than 10 days). CKD group was subclassified regarding the length of stay in pre-dialysis care in 10 to 45 days (10-45), 45 to 90 days (45–90), and more than 90 days (>90). Demographic variables, vascular access, and laboratory variables were compared between CKD and No CKD, and within subgroups during the observation period. Values are expressed in mean ± SD. Values compared using Student t-test or ANOVA accordingly.
Results: CKD patients were older than No CKD (CKD: 61.5 ± 16.6 vs NoCKD: 60.6 ± 17.2; p = 0.02), with lower male prevalence (CKD: 57.5% vs NoCKD: 60.2%; p=0.001). No significative differences in prevalence of diabetes were found. Patients under pre-dialysis treatment showed a higher rate of PD referrals (CKD: 44.6% vs NoCKD: 7.3%; p <0.0001). Regarding vascular access, a higher percentage of CKD patients started dialysis with definitive access (AVF or AVG) (CKD: 47.9% vs NoCKD: 31.5%; p <0.0001). In the same way, prevalence of definitive accesses was higher in patients with longer CKD stay (10-45: 38.4%, 45-90: 57.3%, >90: 50.2%; p<0.0001). Within patients who started treatment with a catheter, a higher percentage of CKD patients already had a fistula or graft performed at treatment start (CKD: 7.3% vs NoCKD: 2.7%; p <0.0001). EPO prescription was higher as the time of follow-up was longer (10-45: 3.3%; 45-90: 7%, >90: 14.9%; p<0.0001). As expected for CKD patients haemoglobin was higher and ferritin was lower (Table 1). Though TSAT, Calcium, and Albumin were significative different between CKD and No CKD, the difference was not clinically relevant. Phosphorus and iPTH was higher in CKD patients and creatinine clearance calculated by MDRD was lower in those patients, opposite of expected (Table 1). Though older and male patients are more likely to have CKD follow-up. Pre-dialysis treatment has a deep impact on PD referral, EPO prescription, type of vascular access at admission, and ready-made vascular access at treatment start. Some laboratory results were not as expected, maybe due to non proper medication accessibility or inadequate financial support at predialysis stages. Even though, CKD follow-up is crucial to prepare patients for a better start of renal replacement therapy.

SEXUAL DIMORPHISMS OF ACUTE KIDNEY INJURY: DIVERGENT PERFORMANCES OF BIOMARKERS OR DIFFERENT MOLECULAR MECHANISMS?
Alexis Piedrafita1, Justyna Siwy2, Ana Belen Sanz3, Paul Bousquet4, Julie Klein5, Melinda Alves5, Audrey Casemayou5, Vincent Minville5, 6, 7, 8
1University Hospital of Toulouse, Department of Nephrology and Organ transplantation, Toulouse, France, 2MosaicDiagnostics, Germany, 3IIS-Fundacion Jimenez Diaz, Laboratory of Nephrology, Spain, 4University Hospital of Toulouse, France, 5INSERM U1297, Toulouse, France, 6University Hospital of Toulouse, Anesthesiology, France, 7IIS-Fundacion Jimenez Diaz, Spain and 8University Hospital of Toulouse, Nephrology and Organ transplantation, Toulouse, France

Background and Aims: Before implementing individualized strategies to prevent or treat acute kidney injury (AKI), identifying clusters of patients with common (or divergent) pathophysiological mechanisms, diagnosis criteria or outcome is of utmost importance.

Method: We compared the characteristics of 1170 male and female patients referred for cardiac surgery with cardiac bypass (CBP) using multivariate logistic regression and propensity score-based analysis. Performances of the candidate urinary biomarkers neutrophil gelatinase-associated lipocalin (uNGAL), [IGFBP7], [TIMP-2] product (Nephrocheck), and a recently developed AKI signature of 204 urinary peptides (PeptAKI) were compared, and sex-dependent individual urinary peptide changes were studied.

Results: In these patients referred for CBP-surgery, incidence and severity (K/DIGO classification) of AKI were similar in men and women (about 25%), even after adjustment of the usual risk factors of AKI including baseline estimated glomerular filtration rate, age, diabetes mellitus, length of CBP and red blood cell transfusion. Performances of uNGAL, Nephrocheck and PeptAKI strongly diverged between males and females. In the overall cohort, as well as in sub-groups of males and females, the multi-markers PeptAKI signature outperformed uNGAL and Nephrocheck. Reanalysis of peptides included in PeptAKI at the single peptide level suggested divergences of AKI mechanisms between sexes. In women, the peptide score-derived risk of AKI strongly relied on peptides indicating kidney inflammation (including SERPINs, SAA1, osteopontin, uromodulin fragments) and hemolysis (HBA1, HBB), whereas a peptide derived from a stress-responsive protective gene in kidney tubular epithelial cells (VGF nerve growth factor) was dramatically less abundant in women developing AKI.

Conclusion: In patients referred for CBP-surgery, significant clinical and biological differences between men and women, as well as sexual dimorphism of AKI biomarkers performances, were identified. Urinary peptide signatures may help to personalize prevention of AKI progression by giving both quantitative and sex-related qualitative information on molecular mechanisms underlying AKI.

ACUTE KIDNEY INJURY IN PATIENTS WITH MULTIPLE MYELOMA SUBMITTED TO AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANT: A COHORT ANALYSIS
Carolina Branco1, Natacha Rodrigues1, Filipe Marques1, Claudia Costa1, Pedro Vasconcelos1, Carlos Martins2 and José António Lopes1
1Centro Hospitalar Universitário Lisboa Norte, Nephrology and Renal Transplantation, Lisboa, Portugal and 2Centro Hospitalar Universitário Lisboa Norte, Haematology, Lisboa, Portugal

Background and Aims: The incidence of most haematological neoplasms has been increasing and with them hematopoietic cell transplantation (HCT) as it provides better survival rates to several of these malignancies. There is a wide range of acute kidney injury (AKI) reported incidence in HCT patients, mostly due to the heterogeneity of AKI definitions and study populations that include
different underlying illnesses. We aimed to evaluate incidence, severity and risk factors of AKI by KDIGO classification considering creatinine and urinary output (UO) criteria in patients with multiple myeloma (MM) submitted to autologous HCT.

**Method:** We conducted a retrospective cohort study including patients with MM submitted to autologous HCT admitted in a tertiary hospital between Jan./2005-Dec./2015 with a 3 year follow-up period. To evaluate AKI cumulative incidence, risk factors and impact on relapse, survival analysis methods considering death as competing were used. Multivariate stepwise analysis using logistic regression was used to evaluate risk factors associated with AKI.

**Results:** 143 patients were included [median age was 50.5 (59.2-63.6) years, 61.5% male and 90.9% Caucasian]. 37.1% had hypertension, 12.6% diabetes mellitus and 10.5% chronic kidney disease (CKD) [median overall baseline eGFR 100.4 (89.5-110.8) mL/min/1.73 m²]. Median percentage of plasma cells on bone marrow aspirate was 30 (17-67)%. serum M-protein 3.3 (2.2-6.6) g/dL and serum titre of the affected light chain 3560 (890-7800) mg/dL. 49 patients had cytogenetic abnormalities. 49% of patients had R-ISS stage I at diagnosis. Median number of previous lines of therapy was 1 (1-2) and the median number of cycles 4 (3-4). 34.5% were previously submitted to radiotherapy. At admission, mean haemoglobin was 11.7 (10.8-12.4) g/dL, neutrophils 3375 (2330-4765) /mm³, serum urea 33 (28-44) mg/dL, uric acid 5 (4.1-6) mg/dL, phosphate 3.4 (3.2-9) mg/dL, LDH 333 (297-390) U/L, albumin 3.9 (3.7-4.2) mg/dL and alanine transaminase 18 (14-27) U/L. Fever (77.6%), exposure to nephrotoxins (74.1%), low grade mucositis (53.9%) and sepsis (26.6%) were common during hospital admission. Cumulative incidence of AKI at 100 days was 49.7% (71 patients) with median time to event of 8 (5-13) days. 85.9% of patients had stage 1 AKI at diagnosis, although 16.4% of these (10 patients) degraded to worse stages. On univariable analysis, the predictor variables with impact on AKI were higher age (p=0.057), higher body mass index (BMI) (p=0.048), HCT-comorbidity index ≥2 (p=0.005), lower baseline eGFR (p<0.001), previous CKD (p=0.001), presence of amyloidosis (p=0.078), higher R-ISS (p=0.002), presence of cytogenetic abnormalities (p=0.055), development of sepsis (p=0.016), fever (p=0.044) and higher grade mucositis (p=0.001), exposure to nephrotoxins (p=0.007), higher neutrophils count (p=0.021), serum urea (p<0.001) and LDH (p=0.002) and lower phosphate (p=0.049), and alanine transaminase (p=0.077). Multivariable analysis showed an independent association of AKI with BMI [HR 1.08 (1.03-1.14), p=0.004], CKD [HR 3.60 (1.55-5.78), p=0.001], amyloidosis [HR 2.73 (1.40-5.33), p=0.001], high grade mucositis [HR 2.35 (1.37-4.02), p=0.002], exposure to nephrotoxins [HR 2.20 (1.08-4.47), p=0.029], leukocyte count [HR 1.01 (1.01-1.01), p<0.001] and serum phosphate [HR 0.57 (0.39-0.84), p=0.004] maintained an independent association with AKI.

**Conclusion:** Our results show that AKI occurs in almost half of the patients with MM submitted to HCT and reinforce the need for prevention, monitoring and early approach to AKI in these patients particularly in those with higher BMI, CKD, secondary amyloidosis, higher leukocyte count and lower serum phosphate at admission, as well as in those that develop mucositis and are exposed to nephrotoxins. We also believe considering both SCR and UO KDIGO criteria for AKI may have increased the reliability of our data, this being the first study to include both criteria in this population of patients.

**Background and Aims:** Several reports showed that some Covid-19 patients tend to have serious and fatal complications related to the kidney and heart. Rationale and mechanisms inducing this pathogenesis is unclear, but it’s more common to happen in patients with hemodynamic instability and refractory severe hypotension related to cytokine storm. It represents an irreversible stage of a sepsis-like illness that induces simultaneous damage to various organs as the myocardium and renal tubules alike the cardio-renal syndrome. The predictors for this injurious effect of COVID-19 on both myocardium and renal tissues might be related to the co-morbidities, late presentation and other factors which need further evaluation. The aim of this article is to study the predictors of cardio-renal syndrome in COVID-19 patients.

**Method:** Our study is a prospective observational study conducted upon confirmed 160 COVID-19 ICU patients admitted from 15th March till 20th May 2020. All patients were subjected to clinical assessment, full laboratory evaluation including PCR for COVID-19 from nasopharyngeal swab and full radiological evaluation.

**Results:** As regards the predictors for cardio-renal syndrome [15-17]; Age showed high statistically significance (P <0.0004). Furthermore, serum creatinine and serum K were statistically significant in patients with cardio-renal affection (P=0.015, 0.021) whereas GFR, D-dimer, need for mechanical ventilation and vasopressors were highly statistically significant with cardio-renal affected patients (P <0.001).

**Conclusion:** Cardio-renal syndrome was common in COVID-19 ICU patients. Hypokalemia, lower GFR on admission, mechanical ventilation, vasopressors, age and D-dimer were significant independent predictors for CRS. Moreover, CRS during hospitalization was associated with an increased risk of in-hospital death.

HYPOCHLOREMIA AS A MARKER OF ALL-CAUSE MORTALITY AND UNPLANNED DIALYSIS STARTS IN A COHORT OF ACUTE KIDNEY INJURY: A 4-YEAR FOLLOW-UP STUDY

Daniela Medina García, Ernesto Francisco Valga Amado, Tania Monzon, Yuliana Stefania Daruiz D’orazio, Cristo Adonay Santana Quintana and Patricia Perez
Dr. Negrin University Hospital of Gran Canaria, Las Palmas de Gran Canaria, Spain

Background and Aims: Serum chloride is an emerging marker of mortality in patients with hypertension, heart failure, sepsis, and chronic kidney disease. The relationship between hyperchloremia and acute kidney injury is well known, especially in critically ill patients. However, the role of baseline hypochloremia in the prognosis of hospitalized patients with acute kidney injury (AKI) remains poorly understood.

Method: Retrospective cohort type study. We included n=243 patients with AKI stage 3 from consultations received by the nephrology department of our hospital between January 1, 2017, to December 31, 2017. The sample was divided into two groups considering baseline serum chloride (Cl−) levels.

Hypochloremia was considered if Cl− < 98 mEq/L. The primary endpoint was a composite variable for unplanned dialysis starts and all-cause mortality.

Results: The mean age was 68 years. Females accounted for 39.5%. The mean baseline sodium was 137±7.2 mEq/l and the mean baseline chloride was 98.9±7.05 mEq/l (Table 1). The mean follow-up of the patients was 21±19.61 months. The incidence of the primary endpoint was n=166 (68.3%). 148 (60.9%) died, of whom 78 (32%) died during their hospital stay. The causes of death were: 30.6% cardiovascular, 12.9% tumor, 44.7% infectious, and 11.8% other. Kaplan-Meier estimates showed lower survival rates in patients with chloride levels below 98 mEq/l (p=0.006, log rank test) (Figure 1).

Conclusion: Patients with AKI stage 3 with lower baseline chloride levels (<98 mEq/L) were more likely to have higher overall mortality and unplanned dialysis starts.

ACUTE CORTICAL NECROSIS IN PREGNANCY IS STILL AN IMPORTANT CAUSE FOR END-STAGE RENAL DISEASE IN DEVELOPING COUNTRIES

Anupma Kaul, Dharmendra Bhaduaria and Narayan Prasad
Sanjay Gandhi Post Graduate Institute of Medical Sciences, Department of Nephrology, Lucknow, India

Background and Aims: Renal cortical necrosis (RCN) is a serious complication of acute kidney injury (AKI) and pregnancy is a clinical state closely associated with it with poor renal outcomes. The incidence is much higher in obstetrical AKI compared to other causes of RCN. Despite better medical care facilities available, this continues to be an important cause of morbidity and mortality in developing countries.

Method: This is a retrospective analysis among all pregnant females presenting with AKI from January 2000 to December 2020 at a tertiary care center in the northern part of India. We looked for the incidence of obstetrical-related RCN in our renal biopsies performed in the last 20 years and to evaluate precipitating factors responsible for RCN.

Results: RCN constituted 8.1% of pregnancy-related AKI cases in our institution. The overall incidence has been declining which was 9.09% from 2000 to 2008 to 8.7% from 2009 to 2014 and 8.1% from 2014-2020. The patient's median age was 28.4 ± 4.6 years. The average time to presentation from the day of delivery was 7.8 ± 3.0 days. The mortality was observed in 10.4% of them with sepsis and multiorgan dysfunction present in all of them. The most common etiology for RCN was found to be septic abortion and puerperal sepsis accounting for - 16.2% each. Postpartum hemorrhage was a cause in 9.67% of patients. The most important cause of RCN was postpartum thrombotic microangiopathy which was observed in 49.5% of patients. Kidney biopsy was helpful in diagnosis in 36 patients while computed tomography scan abdomen alone helped in diagnosis in five patients. Patchy cortical necrosis in histology was seen in 36.7% of patients and morbidity in terms of prolonged hospitalization was seen in 36.7% of patients and morbidity in terms of prolonged hospitalization was seen in 23.4% while dialysis dependency in 63.4% of the study population.

Conclusion: Strategies need to be implemented in reducing the preventable causes for RCN which is not only catastrophic in terms of renal outcomes but also for social and psychological perspectives as well.

RENAL PROGNOSIS IN PATIENTS WITH ACUTE KIDNEY INJURY AND COMPARISON OF THE RIFLE AND KDIGO CLASSIFICATION SYSTEMS: WHAT IS THE ROLE OF DIABETES MELLITUS?
George Aggelis, Margarita Bora, Zoi Alexakou, Emelina Stabiliou, Dimitrios Kourniotis, Athanasia Kapota, Aghla Chalkia, Panagiota Giannou and Dimitrios Petras
General Hospital of Athens Hippokratario, Greece

Background and Aims: Acute Kidney Injury (AKI) is a frequent clinical entity. There are three AKI definition classifications: RIFLE, AKIN and KDIGO. The endpoint of this study is to compare KDIGO and RIFLE regarding the prediction of AKI stage and adverse outcomes and to evaluate the renal prognosis of patients with a history of chronic kidney disease (CKD), who develop AKI during hospitalization. It is a well-known fact that Diabetes mellitus (DM) is the most common cause of end-stage chronic kidney disease (CKD). The epidemiology and outcome of diabetic patients with AKI during hospitalization, needs further study and comparison with the data of non-diabetic patients. As a secondary end point of this study we observed the progression of kidney function and severity of treatment in diabetic patients with stage III AKI (KDIGO) in comparison with the non-diabetic patients.

Method: This is a retrospective epidemiological study where data of 1083 adult patients were examined with AKI, who were hospitalized in various clinics at General Hospital of Athens Hippokratario between January 2021-September 2022.

Results: A total of 1083 patients were registered (63% male, mean age 74.5 ±12.6 years). 42% suffered from diabetes mellitus, 39% from arterial hypertension and 41% from CKD. RIFLE identified fewer patients with AKI than KDIGO (69.7% vs. 100%, p<0.001). Of all patients, 43.1% corresponded to AKI stage 1 (AKI-1), 7.3% to AKI stage 2 (AKI-2) and 46.7% to AKI stage 3 (AKI-3) according to KDIGO. 41.9% of AKI-3 patients underwent hemodialysis. Of the 214 patients on dialysis, 31.8% were not identified as AKI by RIFLE. In addition, patients with a history of CKD showed a higher percentage of AKI-3 (47.1% vs. 39.3% AKI-1, p=0.003 and 13.6% AKI-2, p=0.001) and underwent hemodialysis in a higher percentage (56.6% vs. 43.4%, p=0.002). On the secondary end point 1083 patients, 458 (42.3%) diabetic and 625 (57.7%) non-diabetic were recognized. Hemodialysis was required in 83(18%) diabetic patients and in 132(21.1%) non-diabetic patients. Patients who ended up on end stage CKD requiring chronic hemodialysis or with GFR <15ml/min/1.73 m² one month after hospital discharge were 37.7% and 51%, respectively. More specifically patients with the worst prognosis, who developed end stage CKD or ended up with GFR <15ml/min/1.73 m² one month after hospital discharge, were categorized in three groups according to CKD Stage at hospital admission: in group A) CKD Stage II out of 29, 8 (27.3%) non-diabetics and out of 19, 4 (21%) diabetic, in group B) STAGE IIIa out of 30 patients 5 (16.6%) non-diabetic and out of 15 3 (20%) diabetic and in group C) STAGE IIIb out of 17 patients 8 (47%) non-diabetic and out of 20 6 (30%) diabetic. It should be mentioned that the worst prognosis was observed in patients who were hospitalized for infection out of 30, 16(63%), with prerenal AKI out of 19 patients, 10(53%) and with a cardiovascular event out of 18 patients, 6(33%).

Conclusion: RIFLE criteria identified a lower proportion of patients with AKI compared to KDIGO, while not classifying a proportion of patients undergoing hemodialysis as AKI. Additionally, CKD was associated with worse renal prognosis in hospitalized patients with AKI. Patients with AKI on CKD who required hemodialysis during their hospitalization did not appear to have a worse prognosis at one month after discharge, comparing diabetic with non-diabetic in group A and B. On the contrary there was a significant difference between patients in group C.

RELATIONSHIP BETWEEN CYTOKINE RELEASE SYNDROME AND ACUTE KIDNEY INJURY AFTER CHIMERIC ANTIGEN RECEPTOR T CELL THERAPY IN HEMATOLOGIC NEOPLASMS
Juan Leon Román, Gloria Iacoboni, Sheila Bermejo Garcia, Cecilia Carpio, Andor Vergara Arana, Oriol Bestard Matamoros, Pere Barba and Maria Jose Soler Romeo
Vall d’Hebron University Hospital, Barcelona, Spain

Background and Aims: CAR-T cell therapy is a promising new immunotherapy to treat refractory hematologic malignancies (RHM). Despite the potential benefits, high rates of treatment related toxicity have been reported after CAR-T infusion. AKI occurs between 20-30% after treatment. The purpose of this study was to identify the relationship between the proinflammatory status (CRS, ICANs, and febrile neutropenia) and AKI development.

Method: Medical records of 115 patients treated with CD19-targeted CAR-T cells for refractory hematologic malignancies at HUVH between July 2018 and May 2021 were reviewed. Clinical data was reviewed within 30 days after CAR-T cells therapy. AKI was defined according to the Kidney Disease Improving Global Outcomes (KDIGO) criteria: grade 1, 1.5 to <2-fold of baseline; grade 2, 2- to <3-fold of baseline; grade 3, ≥3-fold of baseline. We performed statistical analysis to identify risk factors for AKI development.

Results: A total of 24/115 patients presented AKI after CAR-T infusion. AKI stage 1 was diagnosed in 17 (15%) patients, AKI stage 2 was diagnosed in 4 (3.5%) patients, and AKI stage 3 was diagnosed in 3 (2.6%) patients. 4/17 patients died in the AKI stage 1 group while 2/3 patients in the AKI stage 3 group. Renal function was recovered in 19/24 (79%) patients within the first month. Chronic kidney disease was present in 13% patients. Among types of CAR-T cell infusion, “investigational product” was infused in 27.8%, tsigengencelucel in 49.6%, axicabtagen ciloleucel in 20%, and brexucabtagene autoleucel in 2.6%. The most frequent complications were cytokine release syndrome (81.9%), febrile neutropenia (67%) and neurotoxicity (28.7%). Tociluzumab was given in 31 (27%) patients for CRS grade ≥2, and 3% of patients were admitted to the intensive care unit 3/36 patients died after CAR-T infusion. Male sex, CAR T-cell construct, ICANs, CRS, and death by any cause were associated with AKI. Only AKI CRS ≥2 (p=0.001) was identified as independent risk factor for AKI.

Conclusion: AKI development is mainly transient and associated with the proinflammatory status after CAR-T cell infusion.

ACUTE KIDNEY INJURY IN INFECTIOUS DISEASE BY CORONAVIRUS IN BRAZIL: A STUDY ON INCIDENCE, RISK FACTORS, AND PROGNOSIS

Bruna Yuasa, Luís Magalhães, Paula Gabriela Sousa de Oliveira, Lais Yokota, Pedro Cardoso, Wélder Zamoner, Andre Balbi and Daniela Ponce

Faculty of Medicine of Botucatu, UNESP, Brazil

Background and Aims: Although diffuse alveolar damage and acute respiratory failure are the main features of COVID-19 disease in its severe form, renal involvement is frequent (4-37%). To assess the incidence of acute kidney injury (AKI) in Brazilian patients hospitalized with COVID-19 and to identify both the risk factors associated with its onset and those associated with its prognosis.

Method: This is a prospective cohort study of patients hospitalized with COVID-19 at a public and tertiary university hospital in São Paulo from March 2020 to May 2021, encompassing the first and second waves of the pandemic. Patients were followed up until the clinical outcome (discharge or death). The evaluation of renal function was performed by measuring serum creatinine and urinary output and the diagnosis of AKI was performed according to the KDIGO 2012 criteria. The occurrence of AKI was established as the dependent variable, using the Chi-Square Test for the comparison of categorical variables and the T Test for continuous variables. Afterwards, a multivariate analysis was performed using the logistic regression model, with calculations of the Odds Ratio (OR), including in the model all the variables that showed association with the outcome (p<0.20). A similar procedure was performed after establishing death as the dependent variable.

Results: 887 patients with COVID-19 were analyzed, 54.6% were admitted to the intensive care unit (ICU) and 45.4% were admitted to the ward. The overall incidence of AKI was 48.1%, more frequent in the ICU (83.8 vs 17.1%, p<0.0001). Upon hospital admission, 487 patients were submitted to urine test I, of which 58.5% had hematuria and 51.5% had proteinuria. The overall mortality was 38.9%. The average time for the diagnosis of AKI was 6 days and AKI KDIGO 3 was the most frequent (60.2%). Acute renal support was indicated in 58.8% of patients. According to logistic regression, the risk factors for AKI were the use of diuretics (OR 2.2, CI 1.2-4.1, p<0.05), mechanical ventilation (OR 12.9, CI 4.3-38.2, p<0.05), presence of proteinuria (OR 1.6, CI 0.9-2.7, p=0.07), presence of AKI (OR 6, CI 2.9-12.2, p<0.05), mainly KDIGO 3 (OR 0.6, CI 0.2-1.3, p=0.2), high D-dimer (OR 1, CI 1, p=0.05), SOFA score (CI 1.35, CI 1.1-1.6, p<0.05) and ATN-ISIS score (OR 996.4, CI 4.8-203271, p<0.05). Finally, the variables that showed the difference in the profile of patients between the two waves of the pandemic were identified, being less frequent in the second wave male gender (OR 0.51, CI 0.35-0.74, p<0.05) and Caucasian ethnicity (OR 0.47, CI 0.2-0.8, p<0.05), and more frequent in the second wave the use of mechanical ventilation (OR 1.57, CI 1-2.3, p<0.05), proteinuria (OR 1.44, CI 1-2.1, p<0.05), higher D-dimer values (OR 1.09, CI 1-1.1, p<0.05) and ATN-ISIS score (OR 40.9, CI 1.7-948.1, p<0.05).

Conclusion: AKI associated with severe COVID-19 in Brazil was more frequent than in the Chinese, European, and North American cohorts, and the risk factors associated with its development are the use of diuretics, mechanical ventilation, VAD, dyslipidemia, proteinuria, CKD, older age, elevated CPK and D-dimer. Mortality was high and higher in patients with arterial hypertension, on mechanical ventilation, with proteinuria, with AKI, mainly KDIGO 3, high D-dimer, and higher SOFA and ATN-ISIS. In the second wave, AKI severity was greater, but mortality was similar to that of the first wave, which may reflect both the effectiveness of vaccines against SARS-CoV-2, as well as the constant learning that frontline professionals have built throughout the pandemic, to provide greater support to its patients.
The neural network achieved a performance of 0.14322 in 6 epochs. Results:

Method: The study included 86 hospitalized patients with acute renal impairment who were divided according to the stage of renal impairment at admission to hospital treatment into three groups. The assessment of acute renal impairment and the classification of disease stages were based on the diagnostic stages by the K / DIGO group. All examined patients were over 18 years of age. In the first stage of the disease it was 12.79%, in the second stage it was 15.12%, and in the third 72.09% of patients. Test methods included clinical physical examination, laboratory evaluation, functional tests, and echonographic examination. Clinical data included demographic, comorbidity and vital parameters, baseline full blood count, biochemistry tests, and echosonographic examination. Further laboratory investigations were performed as indicated clinically thereafter. Spot blood and urine samples were collected from all patients in the morning after overnight fasting. The neural network was created in feed forward back propagation of the connection between the data of 69 patients with 31 parameters. In pattern recognition, the neural network learns to recognize the conditions in which it was decided to send the patient to dialysis 10 or to send to classical treatment 01. The training function analyzed the patients separated in three special categories 80% training, 10% test and 10% validation. The algorithm of the learning function is a scaling gradient that adapts the input data to the output data.

Results: The neural network achieved a performance of 0.14322 in 6 epochs. In a test with the data of 17 patients, it was shown that the neural network indicates for which patients dialysis treatment is a better option that fits with AKI stage 3. For patients with the first and second stages of the disease, conservative treatment is a better therapeutic choice.

Conclusion: This paper deals with a current topic by analyzing data using a neural network algorithm to help assess the stage of the disease in high-risk hospitalized patients with acute kidney injury and select treatment modalities. The conclusions derived from this analysis should help with stage recognition and the selection of treatment modalities for patients with acute kidney injury. Results: A total of 1082 adult patients were recorded with median age 77 years. The majority of them had several comorbidities, 457(42%) diabetic, 424(39%) hypertensive and 442(41%) with Chronic Kidney Disease (CKD). Principal causes of AKI were cardiovascular disease (405;38%), infection (198;18%), gastrointestinal disorders (130;12%) and malignancy (103;10%). Other etiologies comprise obstructive nephropathy (45%;4%), bleeding (363%;3%), surgery (29.3%), cardiovascular surgery (13%;1%) and miscellaneous (123.12%). Management of AKI included fluid resuscitation applied in 405.37% cases, intravenous diuretic therapy applied in 241;22% patients, while 216.20% cases required hemodialysis.

The mean creatinine value at assessment was 3.9±2 mg/dl while 15% of the patients had a normal admission creatinine (<1.3mg/dl). The patients were classified in three groups according to the creatinine levels rise: A) 345 patients at baseline had a creatinine rise of 0.3-0.5 mg/dl, B) 343 had a rise of 0.6-1 mg/dl and C) 394 had a rise of type "Periodic" type "Periodic"> 1 mg/dl. The mean value of hospitalization days for each of the 3 above groups was calculated as 10.8 ± 10.3, 10.7 ± 8.1 and 14.7 ± 11.4 respectively, p<0.05 for the comparisons with the 3rd group.

In comparison, there was no significant difference in the treatment method of AKI between the 2 groups, but Hemodialysis was applied more frequent in the 3rd group (44 vs 46 vs 124 patients, p<0.05 for the comparisons with the 3rd group). Regarding the difference between the creatinine levels on admission and the creatinine levels on discharge, a statistically significant difference was found between the 3 groups (p<0.05) with prevalence of worst discharge creatinine levels to the third group. 15% exited with creatinine <1.3 mg/dl. In a multivariate linear regression model, it was also found that the difference in admission-discharge creatinine levels, diabetes mellitus was an independent factor (p = 0.035) as well as the group categorized based on the increase in creatinine during assessment (p<0.01).

Conclusion: Hospitalized patients in non-nephrology clinics may develop AKI and require different treatment plan as well as management of the primary cause. The heterogeneity of AKI and the need for dialysis as well as the days of hospitalization, underlines the need for close observation, personalized care, vigilance of other specialists and the cooperation with nephrologists.

As it is shown from this study the early nephrology assessment is associated with fewer days of hospitalization and better outcome for the patient's renal function, as well as the severity of the treatment. As the prevalence of chronic kidney disease is rising around the world is of great importance for the patients with AKI to be able to maintain their kidney function.
Septic (16.6%), Mixed Renal Tropism (16.2%), Ischemic (15.5%) and CS (10.9%). Regarding the CS, patients were more often admitted to the ICU (100%; p<0.001) made the least use of corticosteroids (51.6%; p>0.001) and diuretics (12.9%; p=0.016), they made the most use of mechanical ventilation (100%), vasoactive drugs (100%) and dialysis (74.2%; p<0.001). Paradoxically, they were the most obese (67.74% p= 0.011), but had less hypertension (48.4%; p = 0.025), less previous cardiovascular disease (6.45% p = 0.01), and less dyslipidemia (9.68%; p = 0.012). In general, the mixed etiology markedly comes closest to the CS etiology, followed by the MOF. Patients who least needed dialysis were those with septic etiology (18.18% p<0.001). Preliminary tests show an impressive mortality of 69.61%, which is associated with the AKI pathophysiological mechanisms (p<0.0001). CS (87.1%), MOF (87.0%), and Mixed Etiologies (89.1%) are the pathophysiological mechanisms associated with poor prognosis; and Viral Renal Tropism (54.3%), Sepsis (48.3%), and Ischemic Injury (34.1%) are the pathophysiological mechanisms related to the best outcomes.

Conclusion: AKI related to COVID-19 patients are mostly elderly, admitted to ICU, classified as KDIGO 3 and their mortality is notable. Nevertheless, the mortality and the need for dialysis depends on the pathophysiological mechanism their AKI, as CS, MOF and Mixed Etiologies are the pathophysiological mechanisms associated with poorest prognosis; and Viral Renal Tropism, Sepsis, and Ischemic Injury are related to the best outcomes.

PERCUTANEOUS RENAL BIOPSY (PRB) IN METASTATIC RENAL CELL CARCINOMA (mRCC) PATIENTS WITH ACUTE KIDNEY INJURY (AKI) ON SYSTEMIC ANTICANCER THERAPY
Tomaž Milanez1,2, Miha Arnol2, Vladimir Premru2, Nika Kojc3, Janja Ocvirk1, Tanja Ovcaricek1 and Edgar Jaimes4
1Institute of Oncology Ljubljana, Ljubljana, Slovenia, 2University Medical Center Ljubljana, Dept of Nephrology, Slovenia, 3Ljubljana, Slovenia and 4Memorial Sloan Kettering Cancer Center New York, Department of Medicine, New York, United States of America

Background and Aims: PRB is relatively contraindicated in patients with solitary kidney (SK) due to the perception that PRB is a risky procedure in this patient population. There are however situations in which a renal biopsy is essential to assess renal toxicity of systemic therapy and/or to identify the underlying kidney disease in the remaining kidney. Data on pathological findings of the kidney disease in mRCC patients receiving systemic anticanter therapy is scarce and it may influence the cancer treatment plan. The main aim of this study was to characterize the pathological findings of PRB in patients with SK undergoing systemic therapy.

Method: We retrospectively analyzed the pathological findings of mRCC patients with AKI who underwent PRB during systemic treatment with antiangiogenic tyrosine kinase inhibitors (TKIs) and/or immune checkpoint inhibitors (ICIs) at the Institute of Oncology Ljubljana between 2018 and 2022. All biopsies were performed under ultrasound guidance by the treating nephrologist in patients with clinical evidence of AKI and no other formal contraindications for PRB.

Results: A total of 11 PRBs were performed in 10 patients, eight of whom had SK (Table 1). Six patients were treated with TKIs and ICIs, three with ICIs and one with a TKI alone. None of the patients had major bleeding or required any additional intervention as a consequence of the PRB. Histology revealed thrombotic microangiopathy (TMA) in three, diabetic nephropathy in three, acute interstitial nephritis in two and focal segmental glomerulosclerosis in three patients. Based on pathological findings, the therapy was discontinued after seven PRBs. One patient with TMA showed progressive loss of renal function (RF) after discontinuation of antiangiogenic therapy while the other two had either stable or improved RF.

Conclusion: Our results indicate that PRB is a safe procedure in patients with SK undergoing systemic treatment for mRCC. The pathological findings in our patients guided the decision either to continue or to discontinue the treatment, which resulted in improvement or stabilization of RF in the vast majority of patients. This study suggests that in patients with SK, PRB can provide important information, which may have a significant impact on the oncological and the nephrological therapeutic approaches.

**mean (standard deviation)
Without AKI compared to patients with AKI (22.01% vs 16.69 ± 4.5% respectively). The Kaplan-Meier curve illustrated longer survival in patients with AKI (Log-rank test: X² = 15.41; p = 0.0001).

Conclusion: Renal impairment in COVID-19 patients occurs in significant percentage, and it is a factor of poor prognosis. The severity of the disease itself is emphasized as main contributing mechanism in the occurrence of AKI, and the lower blood saturation at admission is the strongest mortality predictor, outreaching the significance of the AKI itself.

PREDICTIVE ADMISSION RISK FACTORS, CLINICAL FEATURES AND KIDNEY OUTCOMES IN COVID-19 HOSPITALISED PATIENTS WITH ACUTE KIDNEY INJURY
Alek桑sandra Canevska Taneska, Irena Rambabova-Bushljetik, Zhakilina Shterio娃- Markovska, Mimoza Milenkova, Adriana Spasovska Vasilova, Vladimir Pusheski, Lada Trajcheska and Goce Spasovski
University Clinic of Nephrology, Medical Faculty, St Cyril and Methodius University, Nephrology, Skopje, Republic Of North Macedonia

Background and Aims: Kidneys in COVID-19 patients demonstrate high vulnerability and acute kidney injury (AKI) is recognized as a cause of poor outcome and high mortality, in those requiring hospitalisation. The aim of our study was to assess the predictors and rate of AKI involvement among COVID-19 hospitalised patients at the day of admission, and to see the impact of AKI on patient's prognosis and life expectancy.

Method: We analysed admission data of COVID-19 patients, hospitalized in a tertiary nephrology hospital, during the first pandemic wave. Outcome data were recorded, including the need for renal replacement therapy (RRT) and inpatient mortality at 30 days.

Results: Out of 115 admitted patients included into the final analysis, 62(53.9%) presented with AKI, 21(39.3%) met KDIGO criteria for stage 1, 7(11.3%) for stage 2 and 34(54.8%) for stage 3 of AKI. RRT was required in 26 patients (22.6% of total, 41.9% of all AKI). From the discharged patients, AKI has been resolved in 76% and no need of RRT following hospital discharge was noted. Pre-existing CKD was associated with a 13-fold risk of AKI (OR 13.04; 95% CI:3.85–44.06, p = 0.009). Pre-existing CKD, that were followed by the nephro-obstetric clinical team were recorded, including the need for renal replacement therapy (RRT) and perinatal outcomes between 2011 and 2022.

Conclusion: Renal impairment in COVID-19 patients occurs in significant percentage, and it is a factor of poor prognosis. The severity of the disease itself is emphasized as main contributing mechanism in the occurrence of AKI, and the lower blood saturation at admission is the strongest mortality predictor, outreaching the significance of the AKI itself.

PREGNANCY-RELATED ACUTE KIDNEY INJURY: 10-YEAR SERIES OF A NEPHRO-OBSTETRIC CLINIC
Estela Nogueira1, Nadiesda Perez1, Iolanda Godinho1, Mónica Centeno2, Luisa Pinto2 and José António Lopes3
1 Centro Hospitalar Universitário Lisboa Norte, EPE, Nephrology and Renal Transplantation, Lisbon, Portugal and 2 Centro Hospitalar Universitário Lisboa Norte, EPE, Obstetric, Gynecology and Reproductive Medicine Department, Lisbon, Portugal

Background and Aims: Pregnancy-related acute kidney injury (P-AKI) is a rare complication of pregnancy associated with significant maternal and fetal morbidity and mortality. Its incidence has progressively decreased worldwide with the improvement of obstetric care, but recently some developed countries have noticed an increase in its incidence. Adjusted definition of AKI in pregnancy is lacking, making its incidence difficult to ascertain. Herein, the authors retrospectively evaluated the causes and outcomes of P-AKI patients surveilled by the nephro-obstetric clinical team.

Method: Retrospective analysis of maternal, obstetric and perinatal outcomes of P-AKI patients, that were followed by the Nephro-obstetric clinical team between 2011 and 2022.

Results: We evaluated 29 patients, with mean age of 32 ± 6 years [17 – 42], 19 Caucasian and 9 Black, 17 nulliparous, 16 hypertensive, 7 diabetic, 1 with HIV, and 1 with systemic lupus erythematosus. Only 12 patients had CKD and 3 were renal transplant patients. In 2/29 patients P-AKI occurred before 20 weeks [15-17] due to obstructive uropathy and pregnancy hyperfiltration in a CKD G3 patient. After 20 weeks of gestation, P-AKI occurred in 27/29 patients (mean 32 weeks; range 21-41weeks), with mean SCr of 3.1 mg/dl [1.8-4.5] in previously CKD patients and mean SCr of 2.4 mg/dl (1.2-5.8 mg/dl) in the patients with normal renal function. Regarding the severity of P-AKI, 16/27/6 patients developed AKI stage 1/2/3 (KDIGO), respectively. Causes of P-AKI after 20 weeks in patients with normal renal function were preeclampsia (PE; 8/14), HELLP syndrome (1/14), hemorrhagic shock (1/14), severe hypercalcemia (1/14), corticosteroid nephrosis due to hypervolemia and nephrotoxic agents (1/14). All patients had full renal recovery. In renal transplant patient P-AKI was related to PE (2/3), sepsis (1/3) and probable calcineurin inhibitor toxicity (1/3). Regarding CKD patients, P-AKI was caused by PE (6/10), hyperfiltration of pregnancy (3/10) and allergic interstitial nephritis (1/10). The need for renal replacement therapy occurred in 7/29, and only 2/7 became dialysis dependent (both with previous CKD diagnosis). De novo or worsening proteinuria occurred in 15/29 (3975 g/day; 431-14000 g/day) and 10/29 patients (mean 6227 mg/day; 681-14937 mg/day), respectively. Regarding fetal outcomes, there were 2 stillbirths, mean gestation duration was 33 weeks (25-41 weeks), mean birth weight 1947 g (550-3950 g) and mean Apgar 1/5/10 was 8/9/10, respectively. Cesarean was performed in 19/27 patients and 7 newborns were admitted to the neonate care unit due to prematurity.

Figure 1: Kaplan-Meier survival curve: patient in-hospital survival among patients with and without AKI.
Conclusion: In a tertiary referral center, P-AKI was associated to a wide range of causes, frequently required a multidisciplinary approach and was associated to significant worse maternal, obstetric and perinatal outcomes.

CALCICUM EXCRETION FRACTION AS AN EMERGING PARAMETER FOR AN ACCURATE DIFFERENTIAL DIAGNOSIS OF ACUTE KIDNEY INJURY
Maria Alejandra Cortiñas Aranzábal, Loreto Mariscal de Gante Sánchez, Laura Salanova Villanueva, Pablo Ruano and Borja Quiroga

Hospital de La Princesa, Madrid, Spain

Background and Aims: Urinary parameter determination is an essential tool for differentiating acute kidney injury (AKI) etiology. The most used ion in clinical practice is sodium (and its excretion fraction, NaEF), followed by urea (UreaEF) (that is useful in certain circumstances such as diuretic treatment). However, tubular transport includes other anions and cations that have not been widely studied. In the present study, we aim to evaluate the relation between AKI etiology (i.e. functional vs acute tubular necrosis) and calcium excretion fraction (CaEF).

Method: This is a transversal study including consecutive patients with diagnosis of AKI. Patients with suspicion of non-functional or ATN etiology (such as those with proteinuria, hematuria) were excluded. At admission, we collected epidemiological data, comorbidities and active treatments. AKI etiology was determined based on urinary parameters (sodium, urea) and recovery pattern of kidney function after treatment instauration. We compared CaEF in patients with ATN and functional AKI in the whole sample and among patients with and without previous CKD and diuretic prescription.

Results: We included 94 AKI episodes (55% female, 76±15 years). Forty-five (48%) patients had chronic kidney disease (CKD) at baseline and 56 (60%) were receiving treatment with diuretics. Of the 94 AKI, 78 (83%) presented an ATN pattern and 16 (17%) were catalogued as ATN. Median CaEF was 1.09 (0.63-2.58) %. CaEF was associated to the etiology of AKI. In patients with functional AKI, median of CaEF was 0.95 (0.60-1.84) % in contrast to ATN (2.33 [1.22-7.27] %)(p<0.001). CaEF presented a positive and significant correlation to NaEF (ρ 0.574, p<0.001) and UreaEF (ρ 0.409, p<0.001). An adjusted regression model including the presence of CKD at baseline and diuretic treatment showed that CaEF independently predicted ATN (OR per 1% increase 1.42, 95%CI [1.16-1.75], p<0.001). In patients without CKD, CaEF predicted ATN (OR 1.61, 95%CI [1.13-2.28], p = 0.008), in contrast to the cohort with CKD where only a trend was demonstrated (OR 1.29, 95%CI [0.99-1.69], p = 0.057) (Figure 1). CaEF also predicted ATN irrespective of the diuretic prescription at baseline (OR 1.35, 95%CI [1.01-1.74], p = 0.018 for diuretic users and OR 1.57, 95%CI [1.06-2.32], p = 0.025 for non-diuretic users) (Figure 1). Receiving operator curves (ROC) demonstrated a 0.712 area under the curve (AUC) of CaEF >1.6% for ATN, that was the best value for diagnosis in terms of sensitivity and specificity. CaEF>1.6% predicted ATN (OR 8.09, 95%CI [2.32-28.2], p = 0.001) after adjusting for the presence of CKD at baseline and diuretic treatment.

Conclusion: CaEF could help in the identification of the AKI etiology as higher values (i.e. >1.6%) are independently associated with ATN.

THE ANTI-AGING FACTOR, α-KLOTHO EXPRESSION DURING HUMAN PREGNANCY AND ITS COMPLICATIONS: PREECLAMPSIA AND SMALL-FOR-GESTATIONAL-AGE NEONATE
Farid Nakhoul1,2,3, Sabreen Shehada 4, Hagar Tadmor 5, Nardeen Khateeb6, Evgeny Farber7 and Yuri Perlita8

1 Cardiovascular Research lab, Nephrology, Nahariya, Israel, 2The Galilee Medical Center, Cardiovascular Research Lab Cardiology Department, Nahariya, Israel, 3The Galilee Medical center Nahariya, Cardiovascular Research Lab Cardiology Dept, Israel, 4Baruch Padeh Poriya Medical Center, Diabetes & Metabolism Lab, Israel, 5Baruch Padeh Poriya Medical Center, Diabetes & Metabolism lab, Israel, 6Baruch padeh Poriya Medical center, Gynecological and Obstetrics Department, Israel, 7Baruch Padeh Poriya Medical center, Nephrology, Israel and 8Baruch Padeh poriya medical center, 2Gynecological and Obstetrics Department, Israel

Background and Aims: Pre-eclampsia (PE) is defined as arterial hypertension associated with proteinuria and may cause dysfunction of vital organs as kidney, liver, brain and other organs. PE is consider as the leading cause of maternal and perinatal morbidity worldwide [1,2]. IUGR definition is abnormal fetal growth compared with growth potential of a specific infant. α-Klotho (αKL) protein has three isoforms: a single transmembrane (mKL) form, a shed soluble form, and a secreted soluble circulating protein (sKL). mKL is expressed in the kidney and placenta. Nowadays, αKL levels correlation to pregnancy or pregnancy’s complications, such as pre eclampsia (PE) or intra-uterine growth restriction (IUGR) is not clear. The research goals were to monitor αKL concentrations during pregnancy and to investigate its expression alterations in correlation to pregnancy complication [3,4,5].

Method: The research included 49 participants, recruited at the Baruth Padeh Poriya medical center, Obstetric Department. The participants were divided into two groups: healthy and complicated pregnancy (PE, IUGR or both). Blood and urine samples were collected during pregnancy and post-delivery (PD). Placental samples were subjected to biochemical (WB) and Elisa, morphological (H&E) histological (IHC) staining and genetic analysis (qPCR). αKL activity was assessed using specific assigned Elisa kit.

Results: sKL during pregnancy show constant concentration that was similar in both healthy and complicated pregnancy. Significant decrease was measured in PE in sKL concentration at PD compared to its level during pregnancy. αKL activity was dramatically reduced in complicated pregnancies compared with healthy pregnancy during and PD. Placental tissue section staining presents decrease in mKL level in the placenta of complicated pregnancy group compared with healthy group. Additionally, we found significant decline in the expression of mRNA of mKL in PE/IUGR placenta compared with healthy group.

Conclusion: sKL level was similar in both healthy and complicated pregnancy, our results suggest low activity of sKL in complicated pregnancy compared with control. 2. Complicated pregnancy is manifested in decline in mKL, also with low activity of sKL compared with control, and gene expression between healthy and complicated pregnancy. 3. A dramatic and significant

Figure 1: Association between CaEF and AKI etiology in patients with and without CKD and diuretic treatment.
Figure 1: Placental klotho levels in control and PE/IUGR group. A. Representative western blots of α-Klotho protein levels in human placental lysates. Proteins were detected by immunoblotting using antibodies against α-Klotho and GAPDH as a loading control. B. Quantification of total Western blot. Placental m-klotho level was significantly reduced in placental PE/IUGR lysate compared with control. PE n=13 control n=20. The results represent the mean ± SEM. Unpaired student’s t-tests were performed to obtain the p values indicated on the graph **p <0.0001.

decline in NO molecules concentration in urine of complicated pregnancy compared with healthy pregnancy.

EPISODES OF AKI FOLLOWING HOSPITALISATION AND ASSOCIATION WITH ADVERSE OUTCOMES: ANALYSIS FROM A PROSPECTIVE COHORT STUDY
Kerry Horner1,2, Daniela Viramontes-Horner1, Rebecca Packington3, Sue Shaw4, Aleli Akani5, Tim Reilly6, John Monaghan4 and Nick Selby1,2

1 University of Nottingham, Centre for Kidney Research and Innovation, United Kingdom, 2 University Hospitals of Derby and Burton NHS Foundation Trust, Renal Unit, United Kingdom, 3 University Hospitals of Derby and Burton NHS Foundation Trust, Department of Informatics, United Kingdom and 4 University Hospitals of Derby and Burton NHS Foundation Trust, Department of Chemical Pathology, United Kingdom

Background and Aims: AKI is associated with adverse long-term outcomes, including mortality, cardiovascular events and CKD development and progression. Individuals who have sustained AKI are at increased risk of developing further AKI. This analysis presents the association of long-term risk related to recent and further episodes of AKI in a prospective cohort of recently hospitalised individuals.

Method: Two matched cohorts of hospitalised individuals who had survived to at least 90 days after hospital discharge were recruited. The cohorts consisted of people who had sustained AKI during hospital admission (exposed group), and those who had not (non-exposed group), and were matched 1:1 for age, baseline eGFR stage and diabetes. Renal function, albuminuria and new AKI episodes were measured at 3 months, one, three and five years after index hospitalisation. Mortality, further AKI episodes and episodes of heart failure were recorded. Kidney disease progression was defined as decrease in eGFR of ≥25% associated with a decline in eGFR stage. Multivariable analysis was performed with binary logistic regression to assess the associations between repeated AKI episodes and outcomes.

Results: 866 exposed and non-exposed participants were recruited and successfully matched. Over the 5-year follow-up period, 138 (34%) participants in the exposed group had ≥1 further AKI compared with 67 (16%) in the non-exposed group (OR 2.71 [95% CI 1.94 to 3.77]; p <0.001). Independent associations with developing AKI during the follow-up period were AKI during index admission, baseline eGFR, albuminuria at 3 months and smoking
status. Binary logistic regression, including all matched participants, showed that AKI during follow-up was independently associated with 5-year kidney disease progression (adjusted OR 2.49, 95% CI 1.42-4.37, p = 0.002), mortality (adjusted OR 3.076 95% CI 2.039-4.639, p < 0.001) and episodes of heart failure (adjusted OR 5.234 95% CI 3.355-8.164, p < 0.001). There was an additive effect, with the frequency of adverse outcomes increasing as number of AKI exposures increased (Table 1). Exposure to AKI during index admission or follow-up episodes conferred similar risk of kidney disease progression. AKI during the follow-up period had a stronger association with mortality and heart failure episodes than AKI during the index admission in this survivor cohort.

### Table 1: Incidence of kidney disease progression, mortality and heart failure episodes after 5-years follow up, according to number of time points during index admission and follow-up in which AKI episodes occurred.

</tbody>
</table>

Conclusion: Previous AKI episodes were associated with increased frequency of future AKI episodes. AKI episodes during follow up period were independent associated with adverse outcomes regardless of AKI exposure during index hospitalisation. Increasing number of exposures to AKI had an additive effect on the proportion of individuals showing kidney disease progression, mortality and heart failure episodes. In this cohort of AKI survivors, AKI during the follow-up period had a stronger associated had with these outcomes than exposure to AKI during the index admission. A strategy for improving long-term outcomes in AKI survivors may be improving the identification of those at greatest risk of future AKI and strategies to prevent or optimise early detection and management.

**TWO-YEAR INPATIENT ACTIVITY OF A DEDICATED ONCOBASED NEPHROLOGY DEPARTMENT**

*Nidia Marques*¹, *Sara Cardoso Fernandes*², *Hugo Ferreira*³, *Teresa Chiva*⁴, *Inês Coelho*⁵, *Ana Paiva*⁶ and *José Costa*⁶

¹São João University Hospital Center, Nephrology, Porto, Portugal.
²Hospital Curry Cabral, Nephrology, Lisboa, Portugal and ³Instituto Português Oncologia do Porto Francisco Gentil, EPE, Nephrology, Porto, Portugal.

**Background and Aims:** Oncoonephrology is a rapidly evolving nephrology subspecialty that focuses on the interaction between cancer and the kidney. Our aim was to describe the clinical activity of a Nephrology Department in a cancer care center, in a 2-year period.

**Method:** We retrospectively analyzed the patients observed by the Nephrology Department at our center between 2021 and 2022. Demographic, clinical and laboratory data were collected. The statistical analysis was performed with SPSS software.

**Results:** During the 2-year period, there were 26,015 admissions, 636 of which required a Nephrology observation. Sixty-two percent were female; the mean age was 68 years (SD 12.4) with a median Charlson Comorbidity Index of 7. Most cancers were from gastrointestinal (24.1%, n = 153) or urologic origins (22.3%, n = 142), 37% had metastatic disease. Hematologic malignancies accounted for 12.1% of patients (n = 77). Nearly 44.5% of patients (n = 283) had chronic kidney disease (CKD), 20.8% (n = 59) of which were on hemodialysis (HD). Urinary tract obstruction (23.3%), cardiovascular risk factors (17.3%) and nephron loss (10.6%) were the most common causes of CKD. The main reasons for admission were renal dysfunction (23.7%; n = 151), infectious complications (23.3%, n = 148) and elective surgery (20.3%, n = 129). Of the patients observed, 40.7% (n = 259) had acute kidney injury (AKI). 23.3% (n = 148) acute-on-chronic kidney disease and 11.8% (n = 75) hydro-electrolytic disorders. Ten patients (1.6%) were evaluated for nephritic syndrome (NS) or rapidly progressive renal failure (RPRF). Among AKI patients, intrinsic causes were the most prevalent (48.7% of all cases), with sepsis and ischemic and toxic acute tubular necrosis being the most frequent. Pre-renal and post-renal etiologies occurred in 29.7% and 21.6% of cases, respectively. Gynecological and prostate tumors were the main neoplastic cause of post-renal AKI. There were 5 TMA cases in allogenic stem cell transplanted patients or treated with gemcitabine and six cases of acute interstitial nephritis, the majority immune check-point inhibitors-related. Over 54% (n = 142) of patients presented with AKI stage 3. About 13% (n = 34) needed renal replacement therapy (RRT), mainly continuous or hybrid techniques (58.8%; n = 20), and only 38% (n = 13) recovered renal function. The group of acute-on-chronic CKD patients included mostly stage 3b and 4 CKD. Most of them (54.1%; n = 80) had an intrinsic cause for kidney dysfunction. There was an equal distribution between stages of AKI severity. About 5% (n = 8) needed RRT and only two of those recovered. Hyponatremia was the most common electrolyte disturbance (56%; n = 42), followed by hypercalcemia (17.3%; n = 13). Over 40% of all cases of hyponatremia occurred in patients with metastatic lung cancer, probably related with the high prevalence of SIADH in this population. All but two patients with NS or RPRF underwent kidney biopsy. Among the patients with NS, its etiologies were: focal and segmental glomerulosclerosis secondary to pemiprodramine (n = 2), podocytopathy related to pazopanib (n = 1), paraneoplastic membranous nephropathy (n = 1), AL amyloidosis (n = 1) and TMA secondary to gemcitabine (n = 1). The causes of RPRF were ANCA-negative small vessel vasculitis, crescentic glomerulonephritis (GN) related to pembrolizumab and TMA. We also followed two patients with acute kidney disease, one with ATN secondary to bisphosphonates therapy and other with paraneoplastic fibrillary glomerulopathy. The median duration of hospitalization was 10 days (IQ 7.0 – 20.8), with median Nephrology follow-up time of 5.5 days (IQ 3.0 – 9.0). The overall mortality rate was 21.5%, and it was even higher on the subgroup with AKI (27.4%; p = 0.03). About 44% (n = 219) of patients were referred to outpatient Nephrology follow-up, at discharge.

**Conclusion:** Our data provides a picture of the rich inward activity developed at our cancer center by the nephrology team. The complexity of these patients highlights the importance of a multidisciplinary approach in their management. No surprisingly, there was a high mortality rate, which was even higher in the AKI-patients subset.

### #6489

**UNI-494 DOES NOT SIGNIFICANTLY AFFECT RAT RESPIRATORY FUNCTION**

*Guru Reddy, Pramod Gupta, Atul Khare and Shalabh Gupta*

Unicycive Therapeutics, Inc., Los Altos, United States of America

**Background and Aims:** Nicorandil, a selective mitochondrial ATP-sensitive potassium channel activator, may be beneficial for several disease states, including acute kidney injury. However, its clinical use is limited by serious gastrointestinal side effects and rapid absorption and elimination. UNI-494, a novel nicorandil prodrug designed to improve its pharmacologic properties, may increase the short half-life and improve the safety profile of nicorandil. We present safety results from a safety pharmacology study evaluating the effects of UNI-494 on respiratory function in a rat model.

**Method:** The effects of UNI-494 on respiratory function (peak inspiratory and expiratory flow, inspiratory and expiratory time, minute volume, and respiratory rate) were evaluated using whole body plethysmography test in 4 groups of male Wistar Han rats (n = 8 per group). In addition to a control group, 3 test groups were administered doses of 2, 20, or 200 mg UNI-494/kg. Airway function parameter data generated were acquired using specialized EMKA Technologies software (IOX version 2.9.5; DATANLYST version 2.6.1) connected to Emka plethysmographic equipment. Recordings were taken 3 hours before and 4 hours after administration of the control and test items. Effects were reported at 0, 10, 15, 20, 30, 60, 90, 120, 180, and 240 minutes after administration.

**Results:** UNI-494 had no relevant effects on rat respiratory function over the 240-minute test period at any dose (2, 20, or 200 mg UNI-494/kg). There were small but insignificant differences in peak inspiratory and expiratory flow (Figure 1, 2), minute volume, respiratory rate, and inspiratory and expiratory time between the control group and the 200 mg UNI-494/kg group.

**Conclusion:** Rat respiratory function was not significantly affected by UNI-494. Future studies should continue to evaluate the safety and efficacy of this novel drug.
CARDIORENAL SYNDROME TYPE 1 IN CHILDREN AFTER SURGICAL TREATMENT OF CONGENITAL HEART DISEASE USING CARDIOPULMONARY BYPASS
Ainamkoz Amanzholova1, Tatyana Ivanova-Razumova1, Bolat Bekishev1, Marina Morenko2 and Nilufar Jabayeva1

1National Research Cardiac Surgery Center, National Research Cardiac Surgery Center, Astana, Kazakhstan and 2Medical university Astana, Astana, Kazakhstan

Background and Aims: According to recent data, acute kidney injury (AKI) after pediatric cardiac surgery is a significant postoperative complication that occurs in 35-64% of children (1,2) and is associated with increased hospital mortality and unfavorable short-term outcomes. The problem of acute kidney injury in children after cardiac surgery remains relevant, despite the development of modern technologies and methods. Complications after pediatric cardiac surgery have serious negative consequences, prolonging the days of stay in the pediatric intensive care unit (PICU) and increasing mortality (3). The aim of the study is to analyze the frequency of AKI in children after open-heart surgery for congenital heart defects (CHD) using cardiopulmonary bypass (CBP).

Method: We conducted a retrospective analysis of 402 medical records of patients hospitalized in the ICU of JSC NRCSC Astana, Kazakhstan, from January 2018 to December 2022. Inclusion criteria: Children under 18 with CHD who underwent open-heart surgery for congenital heart defects (CHD) using cardiopulmonary bypass (CBP).

Results: The analysis included the total number of patients - 402 patients. The frequency of AKI was 15.6% (63 out of 402). Among the patients who developed AKI: boys - 45 (71.4%), girls - 18 (28.5%). The age distribution is as follows: children under 1 month among AKI - 50 (79.3%), under 6 months among AKI – 13 (20.6%), under 1 year among AKI – 5 (7.9%). According to the statistical analysis results, the complication depends on the type of operation, as there is a statistical significance of the differences in the groups (p = 0.046). However, the type of operation (p = 0.35) does not matter for the outcome. Also, the children's weight (p = 0.082) has no statistical significance on the number of complications and the outcome. The sex of children has a statistical significance for complications; in boys, it is significantly higher (p = 0.05).

Conclusion: According to our data, the frequency of AKI developed in 15.6% of patients after surgical treatment of CHD using CBP. The overall mortality rate is 19.9%, with boys having a higher risk. Thus, the frequency of AKI is influenced by many factors before, during and after surgery. Therefore, developing preventive measures is a priority for improving the cardiac surgery results in children.

INITIAL EMERGENCY ROOM 6-HOUR URINE VOLUME IS AN IMPORTANT FACTOR FOR THE SURVIVAL OF CRITICALLY ILL PATIENTS UNDERGOING CRRT

Background and Aims: It has been little known whether initial emergency room factors affect survival or renal function in critically ill patients undergoing continuous renal replacement therapy. We examined whether...
initial factors in ER impact survival and renal recovery in critically ill patients undergoing continuous renal replacement therapy. Method: The study was a single-center, retrospective study of 332 patients for critically ill patients admitted to ICUs for continuous renal replacement therapy via emergency room from March 1, 2018 to May 31, 2021. Clinical parameters including urine output, eGFR, and serum NGAL were identified. The primary outcomes were the 30- and 90-day mortality. Secondary outcomes were the 30- and 90-day dialysis-free duration. Results: Low urine output (LUO, defined as < 0.5 mL/kg/hr x 6 hours) group was significantly associated with 30-day mortality and 90-day mortality. Multivariable Cox regression analysis showed that LUO group was significantly more associated with the increased risk of 30-day mortality and 90-day mortality (hazard ratio, 1.935 and 2.141, respectively) compared to high urine output (HOU, defined as ≥ 0.5 mL/kg/hr x 6 hours) group. There was no significant association between 30-day or 90-day mortality and initial estimated glomerular filtration rate (eGFR) plasma neutrophil gelatinase-associated lipocalin (NGAL) levels. In critically ill patients undergoing continuous renal replacement therapy, HOU group and initial eGFR ≥ 30 ml/min/1.73m2 groups was associated with decreased 30-, and 90-day dialysis-free duration. However, serum NGAL had no significant relation with 30-, and 90-day RRT free durations. Conclusion: During admission to emergency room, the initial low urine output is an important factor for 30- and 90-day mortality in Critically Ill Patients Undergoing Continuous Renal Replacement Therapy. #5974 CLINICAL AND HISTOPATHOLOGICAL CHARACTERISTICS OF THE ONCO nephrological POPULATION: A MULTICENTRE PROSPECTIVE OBSERVATIONAL STUDY Giovanni Pintus1, Silvia La1, Alessandra Punzo1, Luca Salomone1, Adolfo Perrotta1, Silverio Rotondi1, Lida Tartaglione1, Francesca Tinti1, Sandro Feriozzi1 and Sandro Mazzaferrino1 1Sapienza University, Department of Internal Medicine, Anesthesiological and Cardiovascular Clinical Sciences, Rome, Italy; 2University of Padua, Department of Medicine - DIMED, Padua, Italy; 3Sapienza University, Department of Translational and Precision Medicine; Nephrology Unit, Rome, Italy; 4Civile Hospital, Nephrology and Dialysis Unit, Nephrology and Dialysis Unit, Viterbo, Italy Background and Aims: Onconephrology is a recently developed discipline aimed at diagnosing and managing renal disease in cancer patients. Few data are available regarding clinical and histological aspects concerning the whole population referred to an onco nephrology clinic. Our study aimed to describe the clinical and histopathological characteristics of these patients and to evaluate indices of renal function recovery, renal damage progression, and mortality; a specific aim was to determine in our cohort the prevalence of acute kidney injury (AKI), chronic kidney disease (CKD) and acute kidney disease (AKD) which included all patients meeting KDIGO criteria for AKD but not for AKI. Secondary aims were the analysis of the immunotherapy subgroup and to determine the rate of immune-related adverse events (IRAEs). Methods: In this prospective observational study, we consecutively enrolled 84 patients for the clinical analysis and 10 patients in two centres for the histopathological study. Clinical assessment in the former group were performed at the first visit (T0), 1 month (T1), 3 months (T2) and 1 year (T3) and compared with a pre-determined baseline. Complete oncological and nephrological assessments were performed. For kidney biopsies, histopathological findings were expressed with quantitative and semi-quantitative parameters. Outcomes were: AKI or AKD complete or partial recovery of renal function (respectively defined as: return to baseline; ≤ 3 mg/dl or > 25% or improvement to a lower stage of AKI); a composite of events (MAKE) based on CKD development or progression or death (only at T3). Results: Our population was predominantly elderly, hypertensive, in metastatic phase (64.2%). M-F; other factors associated with increased cardiovascular risk were: previous AKI (18.8%), diagnosis of type 2 diabetes (25.9%), history of former/current smoker (55.4% and 19.6%), hyperuricemia (mean uric acid 7 mg/dl), previous/current cisplatin treatment (15.5% and 3.6%). The estimated prevalence in our cohort was: AKI 30.1%; CKD 27.7%; AKI on CKD 25.7%; AKD 9.6%. Regarding AKI, 68.4% were stage 1; for CKD, most patients were stage 3A and 3B (28.2% and 46.2%). More than 1/3 of the patients presented with suspended anticancer treatment; complete therapy resume rates were modest. Complete and partial AKI recovery rates at T2 were both ~33%. Renal function was fully recovered in 50% of the AKD patients. During the follow-up, a new episode of AKI was observed in 15.5% of the patients, more frequently in the first 3 months. Patients receiving immunotherapy showed worse renal function (sCr 2.02 vs 1.51 mg/dl at T0, p<.001) and higher mortality (4 vs 0, p<.05); patients with IRAEs (25.8%) presented more frequently with discontinued therapy (Table 1). Of 36 patients with data available at 1 year, 21 (58.3%) presented the outcome MAKE; 11 patients died, 4 in the first three months. No nephrological conditions were found to predict MAKEs; presence of metastasis and female sex were the only predictors with Cox regression. Patients who underwent renal biopsy showed marked heterogeneity in the diagnoses (4 Membranous nephropathy, 1 drug-induced podocyte damage, 1 extracapillary GN after SARS-CoV2 vaccination, 1 Light/Heavy Chain Deposition Disease, 1 Chronic Tubulointerstitial Nephritis, 1 sclerohyalinosis, 1 nonspecific); histopathological data was unremarkable. Conclusion: AKI and CKD occur frequently in the onco nephrological population. These patients are susceptible to new AKI episodes. The absence of AKI recovery and anticancer therapy withdrawal are common, potentially holding negative prognostic value. Particular attention should be paid to patients undergoing immunotherapy, especially when associated with IRAE. A larger number of patients is needed to estimate the impact of nephrological factors in the extended follow-up. #3380 ACUTE KIDNEY INJURY IN NON-CRITICALLY ILL PATIENTS: CLINICAL CHARACTERISTICS AND OUTCOMES Marco Fiorentino, Sebastiano Nestola, Sabrina Carparelli and Loreto Gesualdo University of Bari "Aldo Moro", Nephrology Dialysis and Transplantation Unit, Department of Precision and Regenerative Medicine and Ionian Area (DMePre-I), Bari, Italy Background and Aims: Acute kidney injury (AKI) still represents a major health public concern associated with worldwide growing incidence. Although many studies have been focused on critically ill patients admitted to ICUs, AKI occurs even in non-critical care settings, with similar consequences in terms of short- and long-outcomes. However, epidemiological data and characteristics of AKI outside the ICU are not well investigated. The aim of the present study was to describe main features and outcomes of AKI observed in non-critically ill patients admitted to a teaching hospital. Method: We performed a retrospective analysis including all AKI patients referred to nephrology consultation in the period January-June 2021 at A.O.U. Policlinico, Bari, Italy. Clinical and laboratory data were collected using the hospital software to analyze the main features of AKI episodes, including their occurrence and stages, the need for renal replacement therapy (RRT), rate and factors associated to kidney function recovery (KFR) and in-hospital death. AKI was defined according to KDIGO Clinical Practice Guideline based on creatinine criteria. In addition, we further collect data on renal function after hospital discharge up to 12 months from discharge to assess the risk of AKI-to CKD transition. Results: Among 899 patients referred for nephrology consultation, 415 (46%) were evaluated for AKI. Pre-existing CKD was present in 204 patients (49%). Most of AKI episodes (52.5%) were classified as KDIGO Stage 3, and 54 patients (13%) required RRT (Table 1). In-hospital mortality in our study cohort was 36.9%, particularly higher in patients with pre-existing CKD (Figure 1a), in patients with stage 3 AKI (Figure 1b) and among patients who did not present KFR within 15 days (Figure 1c). Multivariable Cox regression analysis showed a higher mortality risk for advancing age (HR 1.032, 95% CI 1.012–1.053, p = 0.002) and pre-renal AKI (HR 2.823, 95%CI 1.219-6.536, p = 0.015), while KFR after AKI (HR 0.246, 95%CI 0.098-0.615, p = 0.003) was associated to a lower mortality. KFR was observed in 197 patients (47.5%), and the proportion was significantly higher among patients with AKI stage 1-2 compared to stage 3 (stage 1 62.6% vs stage 2 57.6% vs stage 3 36.8%, p<0.001). Higher baseline eGFR (OR 1.025, 95%CI 1.014-1.036, p<0.001) was associated with higher rate of KFR, while the development of severe AKI was independently associated with lower probability of KFR (OR 0.420, 95%CI 0.248-0.711, p = 0.001). Data on follow-up within 6 months after discharge were available in 62 patients: a

Legend: AKI acute kidney injury; CA-AKI community-acquired AKI; CKD chronic kidney disease; HA-AKI hospital-acquired AKI; IQR interquartile range; sCr serum creatinine.

Further reduction of eGFR compared to the discharge was documented in 30 patients (48.4%).

**Conclusion:** AKI represents the main nephrologist’s activity as consultants at our teaching hospital. AKI episodes referred to nephrologists are usually severe and associated with a high mortality rate even outside the ICU. A timely nephrologist consultation is important to limit the incidence and severity of AKI.

Figure 1: In-hospital survival curve stratified according to baseline eGFR (a), severity of AKI (b) and kidney function recovery (c).
#3709 KIDNEY IMPAIRMENT AT DIAGNOSIS IN MULTIPLE MYELOMA: THE NEPHROLOGIST PERSPECTIVE

Gabriel Stefan1, Cinca Simona-Mihaela2, Adrian Dorin Zugraveu3, Corina Chiriac1, and Simona Stancu1

1 Carol Davila University of Medicine and Pharmacy, Bucharest, Romania and 2Nephrology Hospital Dr. Carol Davila, Bucharest, Romania

**Background and Aims:** Kidney impairment (KI) at multiple myeloma (MM) diagnosis ranges between 20 and 50% and is associated with high mortality. Therefore, an important percentage of the newly diagnosed cases of MM come from nephrologists. We aimed to evaluate the new cases of MM with KI diagnosed in our nephrology tertiary care center for presentation features, initial treatment, and survival.

**Methods:** We performed a unicentric retrospective study on 89 consecutive patients newly diagnosed with MM (median age 66 years, 38% male) between 2015-2020. Patients were followed until death or end of study (September 2022), whichever came first.

**Results:** The most common MM type was free light chain (FLC) only (55%) followed by IgG (30%), IgA (14%) and IgM (1%). Kappa FLC was more frequent than lambda FLC (53 vs 47%); the median FLC level was 1760 (IQR 450, 7373) mg/L, and the median narrow plasmocytosis was 30 (IQR 15, 60) %. Among the 89 patients, 81% presented with acute kidney injury, 12% with chronic kidney disease, 5% with isolated proteinuria and 2% with nephrotic syndrome. Baseline median serum creatinine and eGFR were 5 mg/dL and 9 ml/min, respectively. Median proteinuria was 3.3 (IQR 1.3, 6) g/g with median albuminuria of 0.27 (IQR 0.11, 0.66) g/g. More than one third (34%) of the studied patients needed hemodialysis (HD) at diagnosis, and 50% progressed to renal replacement therapy by the end of the follow up period (CKD5D). The most frequent clinical features at presentation were asthenia (75%), followed by bone pain (51%), orthostatic hypotension (14%), peripheral neuropathy (10%), edema (10%) and dyspnea (6%). Arterial hypertension (71%), systemic atherosclerosis (58%), ischemic heart disease (44%) and diabetes mellitus (12%) were the most frequent recorded comorbidities. Treatment with dexamethasone was started by the nephrologist in 74% of the patients at a median dose of 128 (IQR 96, 160) mg, afterwards the patients were referred to hematology for a bortezomib based regime. During the follow up period 58 (65%) patients died; they had higher serum creatinine (5.8 vs 2.5 mg/dL, p = 0.02), needed HD at diagnosis more often (41 vs 20%, p=0.01), had lower serum albumin (3.7 vs 4.4 g/dL, p = 0.001), higher LDH (236 vs 201 U/L, p=0.01) and increased inflammation (C-reactive protein: 13 vs 3 mg/L, p = 0.001). In univariate logistic regression, the risk factors at diagnosis associated with mortality were increased age (OR 1.07, 95% CI 1.03-1.12), atherosclerotic burden (OR 5.51, 95% CI 2.13-14.22), low serum albumin (OR 0.28, 95% CI 0.13-0.63), inflammation (OR 1.05, 95% CI 1.01-1.09), increased LDH (OR 1.01, 95% CI 1.00-1.02) and the need for HD at diagnosis (OR 2.94, 95% CI 1.94-8.26). However, in multivariate analysis only low serum albumin (OR 0.22, 95% CI 0.05-0.90) and the need for HD at diagnosis (OR 10.64, 95% CI 1.71-66.14) were significantly associated with mortality.

**Conclusion:** Patients with MM and kidney impairment at diagnosis are more frequent kappa FLC, present most often as AKI, around one third of them require HD at diagnosis, and half of them progress to CKD5D. Therefore, these patients are a distinct group of MM with a high mortality rate (>60% at five years) who need interdisciplinary care.

---

#3640 IMMUNORELATED RENAL ADVERSE EFFECTS IN PATIENTS TREATED WITH CHECKPOINT INHIBITORS

Avinash Chandra Nanwani, Jonay Manuel García, Germán Pérez Suárez, Ana Ramírez Puga, Selene González Nuez, Fátima Batista García, Saulo Jesús Fernández Granados, Noemí Espanzar Martin and Cesar García-Cantón

C.H.U. Insular-Materno Infantil, Nephrology Section, Las Palmas de Gran Canaria, Spain

**Background and Aims:** Checkpoint Inhibitors (CPI) use has revolutionized cancer treatment. However, Immuno-Related Adverse Effects (IRAE) occur in more than 50% of patients. At renal level, the initial incidence of IRAE was considered low and later studies suggest between 1.4–4.9%. The aim of the study was to describe the incidence of IRAE in a single center, and their outcomes after initiation of treatment.

**Methods:** We retrospectively studied 28 patients (72.4% male, median age 71.1 years, IR: 40.1–87.3), with metastatic neoplasms (22 advanced lung cancer, 4 melanomas, 1 renal and 1 colon) treated with CPI (Pembrolizumab 75%, 21.4% Nivolumab and 3.6% with Pembrolizumab + Iplimumab combination) who developed AKI after CPI use, at the Complejo Hospitalario Materno Insular from January 2016 to March 2022. Demographic, clinical and analytical data were collected, as well as, the evolution of kidney function.

**Results:** Immuno-related AKI occurred after a median of 3.7 months (IR: 0.23–24.0). The median plasma creatinine prior to receiving treatment with CPI was 0.9 mg/dl [IQR: 0.67-1.65]. After initiation of steroids (1mg/kg/day), 85.7% showed recovery of kidney function. Seventeen patients (60.7%) presented complete remission, 8 (26.6%) partial remission, while 3 patients (10.7%) did not recover from kidney function. In patients who did not respond initially to steroid therapy, a renal biopsy was performed (n = 7; 25.9%) showing tubulointerstitial nephritis (TIN) in 5 patients, 1 granulomatous nephritis with poor kidney function evolution, and 1 endocapillary glomeru- lonephritis together with TIN. More than half of the patients who developed immuno-related ARF presented toxicity in other organs (n = 13; 56.3%); being thrombosis the most frequent (n = 3; 10.7%).

At the end, two patients (7.1%) presented complete remission of neoplasms, 6 (21.4%) partial remission, stability was observed in 8 patients (28.6%), the neoplasm progress in 4 (14.3%) and 8 (28.6%) patients died during the follow-up. Finally, the patient median survival was 36.7 months ([IQR 5.7–79.6) post CPI treatment.

**Conclusion:** Immuno-related AKI after use of CPI is low; over two-thirds of patients recovered from total or partial renal function after initiation of steroids. The presence of granulomas in renal biopsy may confer poor prognosis.

---

#4870 MORTALITY OF ELDERLY PATIENTS WITH ACUTE KIDNEY INJURY UNDERGOING CONTINUOUS RENAL REPLACEMENT THERAPY: IS AGE A RISK FACTOR?

Ji Hye Kim1, Mi Ryong Pyo1, Jin Ah Park1, Sang Hoon Eum1, Ji Won Min2, Eun Sil Koh2, Eun Jeong Ko2, Hyung Duk Kim3, Byung Ha Chang2, Seok Joon Shin1, Chul-Woo Yang3 and Hye Eun Yoon4

1Incheon St. Mary’s Hospital, College of Medicine, The Catholic University of Korea, Internal Medicine, Inchon, Rep. of South Korea and 2College of Medicine, The Catholic University of Korea, Internal Medicine, Seoul, Rep. of South Korea

**Background and Aims:** The incidence of elderly patients with acute kidney injury (AKI) requiring continuous renal replacement therapy (CRRT) is increasing. However, there is little evidence on the difference of mortality rates according to age in elderly patients. This study aimed to evaluate the age effect and predictors for mortality in elderly patients with AKI requiring CRRT.

**Method:** A retrospective analysis was performed in elderly patients with AKI who underwent CRRT. A total of 480 patients aged ≥ 65 years were stratified into three groups according to age: youngest-old (age 65 - 74 years, n = 205), middle-old (age 75 - 84 years, n = 217), and oldest-old (age ≥ 85 years, n = 58). The 28-day and 90-day survival rates were compared between three groups and predictors for mortality were analysed.

**Results:** The 28-day and 90-day survival rates were not different between three age groups (P = 0.156 and P = 0.189, respectively). The oldest-old group did not show an inferior survival rate to other two groups. For 28-day mortality, prothrombin time [hazard ratio (HR) = 1.37, 95% confidence interval (CI) = 1.01 – 1.88, P = 0.046] and urine output at the start of CRRT (HR = 0.999, 95% CI = 0.998 – 1.000, P = 0.012) and CRRT duration (HR = 0.89, 95% CI = 0.83 – 0.95, P = 0.001) were predictors. For 90-day mortality, mean arterial pressure (HR = 1.02, 95% CI = 1.00 – 1.03, P = 0.019), admission duration (HR = 0.97, 95% CI = 0.95 – 0.99, P < 0.001) and CRRT duration (HR = 0.96, 95% CI = 0.91 – 0.99, P = 0.036) were predictors. The middle-old group or the oldest-old group did not exhibit higher risk compared to the youngest-old group for 28-day and 90-day mortality.

**Conclusion:** An older age was not a risk factor for mortality in elderly patients with AKI undergoing CRRT. This implicates the importance of active management and application of CRRT in critically ill elderly patients with AKI.

---

#4893 THE INCIDENCE, RISK FACTORS AND OUTCOMES OF ACUTE KIDNEY INJURY AFTER MINOR LOWER LIMB AMPUTATIONS

Stefanie Marie Agius1, Deborah Balzanz1, Kevin Cassar2 and Jesmar Buttigieg3

1Mater Dei Hospital, Nephrology Division, Department of Medicine, 2090, Malta and 2Mater Dei Hospital, Vascular Surgery Unit, Department of Surgery, 2090, Malta

**Background and Aims:** Minor lower limb amputations (to amputations distal to or through the tarsometatarsal joint), are limb and
**Method:** This was a single centre retrospective study involving patients who underwent minor lower limb amputations at Mater Dei Hospital Malta between January and December 2019. Patient and procedure details were obtained from hospital records. Estimated glomerular filtration rate (eGFR) was calculated using the Modification of Diet in Renal Disease formula. Chronic kidney disease (CKD) was defined as per Kidney Disease: Improving Global Outcomes (KDIGO) criteria. AKI was defined using Acute Kidney Injury Network (AKIN) criteria or KDIGO criteria if day 7 serum creatinine was available. Statistical analysis was performed using SPSS Statistics for Windows v21.0 (IBM Corp.).

**Results:** A total of 201 patients were included; males 69.7%, mean age 70.4 ±11.5 years, 87.1% had diabetes mellitus, 71.1% hypertension and 26.4% had ischemic heart disease. Pre-existing CKD was identified in 35.8%; 16.4% CKD stage 3a, 13.4% CKD stage 3b, 5.5% CKD 4 and 1 patient CKD 5. The majority (76.1%) underwent single toe amputations. Surgery was performed under loco-regional anaesthesia in 90% of patients, mostly in view of lower limb ulcers (64.7%) or gangrene (29.4%). A cohort of 54 (26.9%) patients received iodine based contrast within 7 days of procedure, including those who underwent bypass surgery (8%) and endarterectomy (4%). The incidence of AKI after minor lower limb amputations using AKIN criteria was 18.9%. An additional 12 patients were identified using KDIGO criteria (24.9%), however KDIGO criteria could only be applied for 123 patients as the rest did not have a day 7 serum creatinine. Most developed stage 1 AKI (18.4%), one patient developed stage 2 AKI and none developed stage 3 AKI using AKIN criteria. Only 1 patient needed temporary haemodialysis having developed AKI after day 3 post-operatively fulfilling KDIGO but not AKIN criteria. Recovery of kidney function occurred in all patients. All-cause mortality at 30 days, 60 days and 18 months (end of follow-up) was 2.0%, 5.5% and 19.9% respectively. None of the deaths were directly related to the AKI-amputation event. Patients who developed AKI, compared to those who did not, were more likely to have an eGFR <45ml/min/1.73 m² at the time of procedure (39.5% vs. 14.7%, p = 0.001). They were significantly older (73.0 ±10.4 vs. 68.5 ±11.8 years, p = 0.033), and more likely to have underlying chronic obstructive pulmonary disease (COPD) (28.9% vs. 13.5% p = 0.028). Use of loop and/or thiazide diuretics (68.4% vs. 49.1%, p = 0.049), fluorquinolones (71.1% vs. 52.8% p = 0.047) and/or carbapenems (10.5% vs. 2.5%, p = 0.043) was also more frequent in this group. Use of iodine based contrast within 7 days of procedure did not effect incidence of AKI. Hospital length of stay and all-cause mortality were not significantly higher in patients with AKI. An eGFR <45ml/min/1.73 m² was established as a strong independent predictor for the development of AKI (odds ratio [OR] 3.24, confidence interval [CI]: 1.40–7.52, p = 0.006), as were use of fluorquinolones (OR: 3.19, CI: 1.30–7.82, p = 0.012) and day 1 C-reactive protein (CRP) (OR: 1.01, CI: 1.00–1.01, p = 0.009). Cumulative survival censored at the end of follow-up was not significantly lower in patients who developed AKI (log rank: 0.45, p = 0.50).

**Conclusion:** In our study, 18.9% of patients developed AKI after minor lower limb amputations using AKIN criteria. One patient required acute haemodialysis. Age, COPD, diuretics, fluorquinolones and carbapenems were associated with increased incidence of AKI. An eGFR <45ml/min/1.73 m², day 1 CRP and fluorquinolone use were independent risk factors for the development of AKI. In this small patient cohort, AKI was not associated with higher all-cause mortality, and none of the deaths were directly related to the AKI-amputation event.

---

**Method:** This is a retrospective observational study amongst adult hospitalized Dengue patients admitted at a tertiary care hospital between January 2019 and December 2019. We estimated the prevalence of Acute Kidney Injury (AKI) using KDIGO AKIN (Acute Kidney Injury Network) criteria. Outcomes were analyzed during the time of discharge.

**Results:** Out of the 1550 hospitalized patients, majority of the patients were males – 1005 (64.9%). Most common age group was between 20 to 40 years. 85 (5.48%) of the total study patients developed AKI. Older age groups were found to be more at risk for concurrent bacterial infections and higher mortality rate. Most patients had stage 1 AKI (70.1%). Overall mortality in patients with AKI was 20.3% and 80.5% in those requiring dialysis. The incidence of AKI risk was increased by as much as 4.5-fold in the presence of hemocoagulation (or hematocrit > 46.5%). Older age, Male sex, co-existing viral hepatitis, Dengue Hemorrhagic Fever, Dengue Shock Syndrome, Rhabdomyolysis, Multiple Organ Dysfunction Syndrome were found to be independent risk factors for DAKI. Presence of DAKI was associated with higher mortality and longer hospital stay.

**Conclusion:** In our study population, we found a low prevalence of AKI but Mortality was high in patients requiring ICU care and dialysis. Prompt recognition and identification of the at-risk population and administration of appropriate supportive treatment should be aimed to reduce the morbidity and mortality associated with this common and very important tropical disease.
ASSOCIATION OF TRADITIONAL AND NON-TRADITIONAL LIPID ABNORMALITIES WITH RENAL FUNCTION: A SURVEY IN A RURAL POPULATION OF BANGLADESH

Ferdous Azad\textsuperscript{1}, Masud Iqbal\textsuperscript{2,3}, Dk Adhikary\textsuperscript{4}, Tareen Ahmed\textsuperscript{5}, Maa Chowdhury\textsuperscript{2}, Sr Chaudhury\textsuperscript{3}, Ms Hassan\textsuperscript{3}, Sajal Krishna Banerjee\textsuperscript{5} and MI Arslan\textsuperscript{2}

\textsuperscript{1}NIKDU, Bangladesh, \textsuperscript{2}KDRG, Bangladesh, \textsuperscript{3}BSMMU, Bangladesh, \textsuperscript{4}BIRDEM, Bangladesh and \textsuperscript{5}NNFH&RI, Bangladesh

Background and Aims: The traditional and non-traditional lipid have been recognized to be involved in various atherosclerotic disease process. Several studies showed that, there is relation with renal function and dyslipidemia. Early detection of these modifiable risk factors and initiation of treatment may prevent or retard the progression of renal disease. Aim of this study was to evaluate the association of the traditional and non-traditional lipid abnormalities with renal function.

Methods: This cross sectional study was carried out in a rural area of Bangladesh. Renal function was evaluated by estimation of enzymatic creatinine, eGFR (CKD-EPI) and spot ACR. Total cholesterol (TC), triglyceride (TG), LDL and HDL was measured as traditional lipids and Apo-A1, APO-B, Lipo (a) as non-traditional lipids. Traditional dyslipidemia (TDLP) and non-traditional dyslipidemia (nTDLP) means abnormality in any of their components. Other tests include urine microscopy, Hb%, FBS, HbA\textsubscript{1c}, serum albumin and uric acid as additional risk marker.

Results: Total 201 patients were included for analysis. The mean age was 41±13 years and male/female ratio 48:52. Around 48% were overweight. Among these 20% were hypertensive, 14% diabetic, nephropathy in 13% and rest 53% had no known chronic disease. The mean value of creatinine was 0.8±0.5 mg%; eGFR was 94±23 ml/min/1.73m\textsuperscript{2}, ACR was 9.70 (median), TG 182±104 mg/dl, TC 96 ±47 mg/dl; LDL 121 ±39 mg/dl and HDL 38±6. The value of Apo-Al was 1.3 g/l (0.2-13.9), Apo-B 1.04 g/l (0.2-2.6) and Lipoprotein (a) was 17.3mg/dl (1.1-81.8). Mean value of FBS was 6.2 ±2.3 mmol/L, HbA\textsubscript{1c} 6.1 ±1.5%, Hb% 13.5 ± 1.6 g% and albumin was 4.8 ±0.5 mg%. When measured the TDLP was present in 81% and normal traditional lipids present in 19%. Similarly as a whole 50% had nTDLP and non-traditional lipids were normal in other half. Around 16% were free from both TDLP and nTDLP. The eGFR was lower in – TG >150 group than in < 150 (90 ±24 vs. 98 ±21 mg%, p=0.02); TC >200 than <200 (91 ±23 vs. 100 ± 22 mg%, p=0.001); LDL >100 and < 100 (91 ±23 vs. 100 ± 22 mg%, p=0.015) but no difference for components of nTDLP. The ACR was higher (> 30 mg/g) in 76% vs 24% (p<0.001) when TG is > 150 and < 150 mg%; 60% vs. 40% (p=0.05) when TC is > 200 and < 300mg%; and 81% vs. 19% (p<0.04) when LDL > 100 and < 100mg%. No such difference for renal functional parameters for non-traditional lipid components. In this study, eGFR had significant negative correlation with TG (r = -0.34 & p<0.001), TG (r = -0.24 & p=0.001), LDL (r = -0.25 & p<0.001) and only ACR had positive correlation with TG (r = 0.17 & p = 0.012). The nTDL wasn’t associated with altered eGFR or ACR.

Conclusion: In this study it was observed that traditional lipid components were altered in 81% whereas non-traditional lipids were altered in 50% rural subjects. Only the traditional dyslipidemia was associated with lower eGFR and higher ACR.

PLATELET TO LYMPHOCYTE RATIO AND SICKLE CELL NEPHROPATHY

Dieu Merci Betukumesu Kabasende\textsuperscript{1}, Aloni Michel\textsuperscript{1}, Kazadi Orly\textsuperscript{1}, Gini Ehungu\textsuperscript{2} and Longo Mbenza\textsuperscript{3}

\textsuperscript{1}Kinshasa University Clinics, Pediatric Nephrology, Kinshasa, Democratic Rep. of Congo (formally known as Zaire), \textsuperscript{2}Kinshasa University Clinics, Pediatric Hematology, Kinshasa, Democratic Rep. of Congo (formally known as Zaire) and \textsuperscript{3}Kinshasa University Clinics, Cardiology Internal Medicine, Kinshasa, Democratic Rep. of Congo (formally known as Zaire)

Background and Aims: Platelet-to-lymphocyte ratio (PLR) was introduced as cheap and readily assessed biologic markers of subclinical inflammation in sickle cell disease. Microalbuminuria and hyperfiltration, early markers of Sickle cell nephropathy (SCN) have been reported to be associated with platelet-to-lymphocyte ratio (PLR). This association has not yet been assessed in Congolese Sickle cell disease (SCD) children. Therefore, the aim of the present study was to assess the association between PLR and early markers of kidney disease in SCD children living in the Democratic Republic of Congo (DRC).

Method: In this cross-sectional study, we have investigated 175 SCD children from four centers (Kinshasa university clinics, CMMASS, CMD Diamond, and Baiamba Marie Mutumbo Dikembe) that give a comprehensive care to SCD patients. The PLR were calculated from full blood count. Elevated albuminuria and hyperfiltration, as the main outcomes of the study, were defined by urinary albumin/creatinine ratio (ACR) >30 mg/g and estimated glomerular filtration ratio (eGFR) > 130 ml/min per 1.73 m\textsuperscript{2} for females and > 140 ml/min per 1.73 m\textsuperscript{2} for males, respectively. Logistic regression analysis was used to assess the relationship between RPL and early sickle cell nephropathy.

Results: Of the 175 SCD children enrolled, 41(23.4%) and 67(38.3%) of them presented with abnormal albuminuria and hyperfiltration, respectively. RPL > 130 was observed in 90 (51.4%) patients. RPL was strongly, significantly and independently associated with both abnormal albuminuria (aOR 3.381; IC95\% 2.22-2.68; p = 0.000) and hyperfiltration (aOR 2.19; 95\%IC 2.09 - 22.25; p = 0.010).

Conclusion: The present study has shown that nearly fifty two out of one hundred SCD children bear a high platelet to lymphocyte ratio that is strongly and significantly associated with early markers of kidney disease.

REFERENCE
**MANAGEMENT AND OUTCOMES OF SEPSIS ASSOCIATED ACUTE KIDNEY INJURY IN CRITICALLY ILL PATIENTS**

Salma Naouaoui, Mariam Chettati, Wafaa Fadili and Inass Laouad

Mohammed VI University Hospital of Marrakesh, Nephrology Department, Marrakesh, Morocco

**Background and Aims:** Sepsis-associated acute kidney injury (AKI) remains a major cause of mortality in patients with critical illness and has an especially high health-related burden in developing countries. However, only a few clinical studies have focused on the clinical characteristics and prognosis of septic AKI, especially in low-income settings. Therefore, the aim of our study was to describe the clinical profile, management and outcome of critically ill patients with sepsis-associated AKI.

**Methods:** A retrospective observational study of critically ill patients with septic AKI was performed from March 2020 to June 2021 at our university hospital. Sepsis was diagnosed clinically by the presence of acute infection and new organ dysfunction. The presence of AKI was evaluated using the Acute Kidney Injury Network (AKIN) criteria. Patients with preexisting ESRD and those who did not fulfill at least one predefined criterion for AKI were excluded.

**Results:** A total of 105 patients with a median age of 58.9 years (31-78) were enrolled, including 69 and 36 patients with persistent and transient AKI, respectively. The mean SAPS II score was 51.8 (38-77). The primary source of sepsis was mainly abdominal (42.8%). AKI was defined by oliguria in 18 patients (17.1%), by creatinine elevation in 65 patients (61.9%), and by both criteria in 22 patients (21%). Septic AKI was associated with great aberrations in hemodynamics, with 71 patients (67.6%) requiring vasoactive therapy and 65 patients (61.9%) requiring mechanical ventilation. AKI severity according to the AKIN classification scheme was determined to be stage 1 in 32 patients (30.5%), stage 2 in 22 patients (20.9%), and stage 3 in 51 patients (48.6%). Overall, 75.2% of the cohort required renal replacement therapy (RRT). Hospital survival was 63.8% (n = 23) in patients with transient AKI and 43.5% (n = 30) in patients with persistent AKI.

**Conclusion:** Sepsis is the main cause of AKI in intensive care units, accounting for up to 50% of cases. Our results suggest that septic AKI is associated with higher disease severity scores at admission, requirement of vasoactive drugs, need for mechanical ventilation and increased hospital mortality. Further studies are required, especially in developing countries, to implement more preventive measures and therapeutic interventions to decrease CKD progression and mortality in these patients.

**CHANGES OF MEDICAL COSTS AND NUMBER OF USES OF CONTINUOUS RENAL REPLACEMENT THERAPY UNTIL RECENT SIX YEARS IN SOUTH KOREA**

Hyung-Jong Kim1, Jae Hyun Chang2, Sang Hyun Jung3 and Keun Hyung Park4

1Bundang CHA Medical Center, CHA University, Internal Medicine, Seongnam-si, Rep. of South Korea, 2Gil Medical Center, Gachon University College of medicine, Internal Medicine, Incheon, Rep. of South Korea and 3CHA Ilsan Medical Center, CHA University, Internal Medicine, Goyang-si, Rep. of South Korea

**Background and Aims:** Continuous renal replacement therapy (CRRT) is a necessary dialysis treatment method applied to patients with acute renal injury at intensive care unit. In South Korea, the use of such CRRT is increasing, and the cost of health insurance used for CRRT is also increasing. In this study, the pattern and medical costs increase of CRRT usage until recent 6 years were investigated.

**Method:** From 2016 to 2021, the number of CRRT claims was investigated using data from the National Health Insurance Review and Assessment Service. CRRT costs is applied by a resource-based relative value score in Korea. CRRT can be charged as continuous venovenous hemodialysis, continuous venovenous hemofiltration, and continuous venovenous hemodiafiltration depending on the treatment mode. The CRRT cost differs from the very day and the next day’s cost, and the cost of the very day includes the femoral hemodialysis catheter insertion cost, which is higher than the next day’s cost.

**Results:** CRRT medical practice is gradually increasing. The number of CRRT the very day increased from 15,640 cases in 2016 to 20,883 cases in 2021, and it continues to increase from 81,649 cases CRRT the next day in 2016 to 121,376 cases CRRT the next day in 2021. The CRRT relative value score is higher than the conventional hemodialysis (HD) and the CRRT relative value score is 9715 points higher than the conventional HD 1065 points. The total cost of CRRT increased by about KRW 52.5 billion (approximately 38,363,171 dollars) in 2021 from about KRW 17.3 billion (approximately 12,641,578 dollars) in 2016. In addition to CRRT medical practice costs, dialysis fluid, anticoagulant costs, and material costs are added, and so actual CRRT-related costs are more expensive.

**Conclusion:** CRRT is essential and it seems necessary to consider medical practices or medical costs that are important for essential medical care. CRRT is a high-cost treatment method that requires definitive guidelines or consensus on the initiation and discontinuation of CRRT.
COVID-19, RENAL DAMAGE AND ITS EVOLUTION IN HOSPITALISED PATIENTS IN THE FIRST WAVE OF THE PANDEMIC: EXPERIENCE OF ONE CENTRE

Celia Garijo, Guillermo Pereda Bengoa, Esther Najera, Aranzazu Pardo Ruiz, Hermann Hernandez, Marta Artamendi Larrañaga, Elisa Bello, Antonio Gil Paraiso, Fernando Gil Catalinas and Emma Huarte

Hospital San Pedro, Nefrología, Logroño, Spain

Background and Aims: The damage that SARS Cov2 virus exerts at the renal level has been the subject of analysis in many studies. We analysed the extent of Acute Kidney Injury (AKI), possible factors involved and mortality in patients hospitalised with Covid-19 during the first wave of the pandemic. We reassessed renal function, as well as inflammatory and nutritional status of patients 18 months after admission, together with the capacity for recovery of renal function.

Method: Observational and retrospective study of patients admitted to the ward or intensive care unit (ICU) for Covid-19 during the month of March 2020. We defined the stage of renal damage according to the KDIGO guidelines. Among the possible risk factors associated with AKI and mortality in patients hospitalised with Covid-19 during the first wave of the pandemic. We reassessed renal function, as well as inflammatory and nutritional status of patients 18 months after admission, together with the capacity for recovery of renal function.

Results: A total of 576 patients were admitted during the study period, of whom 10.6% were admitted to the ICU (n 61). A total of 45.9% (n 28) had some degree of AKI, the most frequent being grade 2 (22.9%), followed by grade 3 (18%) and grade 1 (4.9%). Of all patients requiring admission to the ICU, 78.6% of those with AKI died. The Odin scale was significantly associated with AKI and mortality, but the Charlson scale was not. The maximum dose of Cisatracurium was significantly associated with AKI. Among the patients admitted to inpatient areas (n 515), 9.9% (n 51) had AKI and 31.4% of these patients died. In most cases the degree of renal damage was mild (82.4% grade 1 vs. 13.7% grade 2 and 3.9% grade 3). When we studied the patients who presented with AKI (n 79), we observed that CK and LDH values were significantly higher, indicating a more inflammatory state. Of the 79 patients, 48.1% (n 38) died, with significant differences in serum CRP and D-dimer levels. Of the 41 patients who survived, we conducted an 18-month follow-up study that only 36.6% (n 15) completed, with a mean age of 69.7 years, 73.3% being male and 20% with previous chronic kidney disease (CKD). At the end of follow-up 86% of them recovered renal function, according to pre-admission figures, including those patients with baseline CKD. Only 13% of the patients who completed follow-up showed a slight worsening of renal function with respect to their baseline situation. We observed differences in the values of calcium, vitamin B12 and vitamin D in the group of patients who recovered renal function compared to those who showed deterioration with respect to their situation prior to admission (p < 0.02). We observed differences in the values of calcium, vitamin B12 and vitamin D in the group of patients who recovered renal function compared to those who showed deterioration with respect to their situation prior to admission (p < 0.02).

Conclusion: The incidence of AKI in COVID patients requiring admission to the ICU was four times higher than in patients admitted to the ward. The severity of renal damage was greater in the ICU, predominantly AKI 2-3 vs AKI 1, with mortality 2.5 times higher than in the ward. The group of patients who develop AKI have an elevation of inflammatory markers, which increases in the group of deceased patients. In ICU, the Odin scale was significantly related to AKI and mortality. - The mortality rate in the group of patients with AKI was high. Most of the patients have recovered pre-admission renal function after 18 months of follow-up, with differences in nutritional parameters such as calcium, vitamin B12 and vitamin D.
SIZE MATTERS: EFFECT OF NUMBER OF TRANSFUSIONS ON ADVERSE RENAL AND CLINICAL EVENTS IN PATIENTS WITH AKI

Isabel Acosta-Ochoa1, Paula Ardua1, Gerardo Aguilar1,2, Armando Coca1, Kenia Cobo1, Carlos Merizalde1, Alicia Mendiluce1 and María Martínez1

1Hospital Clínico Universitario de Valladolid, Nephrology, Valladolid, Spain and 2Hospital Clínico Valladolid, Hematology, Valladolid, Spain

Background and Aims: AKI and anemia independently worsen the prognosis of hospitalized patients, but their association and adverse effects have been slightly studied. We aimed to investigate the effect of transfusions during hospitalization on hard renal and clinical outcomes of patients with AKI. In addition, we tested the influence of the number of transfusions on mortality between pure AKI (pAKI) and AKI-on-CKD (AoCKD) patients.

Method: Retrospective cohorts’ study, of in-patients with AKI attended by nephrology during a 12-month period. AKI severity was categorized by KDIGO-2012 criteria; we searched in a Hematology administrative data base for transfusions (and their number) during the hospitalization period. We analyzed epidemiological and clinical variables and compared the rates of the hard outcomes Length of Stay (LoS), Acute Hemodialysis (aHD), Dialysis Dependence at Discharge (DDD), and in-hospital Mortality (IHM) between individuals that didn’t and received transfusions.

Results: We included 275 individuals, 134 (49%) were transfused; they were older and suffered more DM; with no differences in the ICU hospitalization and Charlson’s Index. See Table 1A. We observed that transfused patients were classified more frequently in AKI Stage-3, had longer LoS, aHD, were more frequently dialysis dependent and their mortality rate was higher. See Table 1B. We compared patients with less or more than 5 transfusions; the latter group showed a higher rate of adverse events than the group of ≤4 transfusions. See table 1C. Figure 1 plots the K-M curve for survival between pAKI and AoCKD groups showing an excess mortality associated with the number of transfusions, especially in the AoCKD individuals.

Conclusion: In our study, we found that patients that received transfusions showed worst clinical and renal results including more severe AKI, longer hospital stay, higher rate of acute HD, dialysis dependence at discharge and mortality. We observed that the appearance of these adverse events was associated in a dose dependent manner with the number of transfusions; for these reasons, we consider that number of transfusions should be included in AKI risk models and calculators. Could optimizing the number of transfusions improve the rate of adverse renal and clinical events? We will need prospective and well-powered studies in order to answer this question and to deepen on the issue of AoCKD and worst clinical outcomes if transfused.

Figure 1: K-M Curve Analysis of Survival, Number of Transfusions in AKI and AoCKD individuals.
Acute Kidney Injury (AKI) is a syndrome characterized by an abrupt drop in glomerular filtration and/or a decrease in urinary output. The awakening to a different kind of AKI that also occurs outside the hospital named community-acquired AKI (CA-AKI) occurred in 1991, however, few data have been published about its epidemiology, risk factors and outcome, especially in low-income countries. The recognition of risk factors for CA-AKI and development of symptom-based risk tool that aims to predict the risk of AKI might be able to avoid delays in its recognizing, improve the timely diagnosis and patient outcomes in this frequent syndrome. We aimed to assess CA-AKI incidence, characteristics and independent risk factors associated with CA-AKI; to evaluate the discriminatory capacity of a clinical score tool to AKI prediction to predict CA-AKI in our sample.

**Method:** We conducted a prospective observational study of general medical admissions to a tertiary hospital in Campinas (São Paulo) between 10th January 2019 and 16th September 2021; we included patients ≥ 14 years, medical suspicion of infection (or confirmed) and/or presence of at least one of the signs or symptoms on admission: fever, dyspnea, decrease in urine output, edema, hypotension, hemodynamic shock, jaundice, petechiae, ecchymosis or decreased level of consciousness. We excluded patients with stage 5 chronic kidney disease at baseline and pre-existing renal replacement therapy (undergoing dialysis and renal transplantation), and also patients with COVID diagnosis. All patients included were assessed utilizing a symptom-based risk score to predict the development of severe AKI, the need for dialysis and mortality. Patients were subjected to complete history taking, socioeconomic and education data were collected. Healthy literacy was assessed using the test of functional health literacy in adults – short version (S-TOFHLA). Predictors of CA-AKI risk were assessed using multivariate logistic regression analysis. Patients were followed up until discharged hospital. The study outcomes were development of CA-AKI, hospital mortality, dialytic need.

**Results:** We enrolled 261 patients. CA-AKI was diagnosed in 65 (25%) patients. The CA-AKI patients were older [59 (51-66) vs. 54 (38-65) years, p = 0.02], had higher basal serum creatinine [0.7 (0.5–0.9) vs. 0.6 (0.5–0.8) mg/dL; p = 0.01], lower baseline estimated glomerular filtration rate (eGFR) [103 (88-113) vs. 109 (97–121) mL/min/1.73 m²; p = 0.01] and lower eGFR on admission [64 (44 – 81) vs. 104 (82 – 116) mL/min/1.73 m²; p = 0.0001]. Liver and heart disease were most common comorbidities in the group CA-AKI [10 (16%) vs. 14 (7%) patients, p = 0.04 and 21 (33%) vs. 39 (20%), p = 0.03, respectively]. The risk score did not show significant accuracy to predicting CA-AKI, however, logistic regression showed that scores ≥ 7 points (OR 95% CI 1.007, 1.044 < 0.01), albuminuria (OR 95% CI 1.282, 6.133 p = 0.010) followed by age (OR 95% CI 1.007, 1.044 p = 0.008) and liver disease (95% CI 1.063, 6.379 p = 0.036) were independent factors associated with increased risk for CA-AKI in our population. A higher percentage of patients in our sample declared household income < $ 719.73 (month) and the CA-AKI group maintained the same distribution. Only 41 percentage of patients in our sample declared household income < $ 719.73.

**Conclusion:** Healthy literacy, education, and social class did not show association with CA-AKI; dialysis needed and mortality were not different between the groups CA-AKI or without CA-AKI. Covariates and factors associated with risk for CA-AKI were age, liver disease and scores ≥ 7 points. The main limitation of our study was not feasible to screen all the patients due to the high numbers seen daily.

**#5624 REMDESIVIR IN COVID-19 PATIENTS WITH KIDNEY DISEASE: A STUDY ON THE RENAL FUNCTION AND OUTCOMES**

Crystal Faye Lagura

Southern Philippines Medical Center, Internal Medicine, Davao City, The Philippines

**Background and Aims:** The COVID-19 pandemic has created a global catastrophe with mortality rates higher in older adults and people with chronic comorbid conditions. In which patients with chronic kidney disease were the most vulnerable population. Remdesivir, an antiviral nucleotide, showed promising results in individuals with COVID-19 infection. However, despite its shortened time to recovery in adults hospitalized with COVID19, individuals with ESRD and high stage AKI were not included in clinical trials, thus when granted an emergency use authorization it was recommended to avoid use in patients with eGFR <30mL/min “unless benefit outweighs the risk”. In this study, in the absence of Molnupiravir, the current drug of choice, we wished to study its safety by determining its effects on renal status of individuals with known kidney dysfunction. The study aims to determine the effect of Remdesivir on renal function and outcomes among COVID19 patients with kidney disease.

**Method:** The study utilized a retrospective research design. The study included patients who were 19 years old and above, with RT-PCR confirmed COVID19 infection treated with Remdesivir and who were confirmed to have kidney disease.

**Results:** 106 patients were included; the mean age was 62.25±13.96 years old, more than half of the population were males. The majority of the population had AKI while the rest had CKD and 25% underwent renal replacement therapy. Most of them were classified with severe and critical COVID infection (Table 1). To determine effects on renal function laboratory parameters were determined at baseline and after completion of treatment. There was an overall significant improvement in eGFR (<0.01), albuminuria (0.013) and in acid-base balance (0.003) and odds ratio showed that none of the demographic, clinical and laboratory profile significantly in-creased the chance of death in terms of overall clinical outcome (Table 2). To determine risk factors of patients that may contribute to patients outcome, odds ratio showed that none of the demographic, clinical and laboratory profile significantly increased the chance of death among patients who took Remdesivir. (Table 3). In terms of overall clinical outcome, this study had a mortality rate of 4.9% (Table 4).

Conclusion: Use of Remdesivir in patients with AKI, CKD and ESRD on dialysis was not associated with further renal function deterioration. Contrary to concerns there was rather an overall significant improvement in EGFR, degree of albuminuria and acid-base balance after treatment regardless of their disease severity and its use in patients on hemodialysis have not shown any detrimental impact on mortality.

INCIDENCE OF ACUTE KIDNEY INJURY IN PATIENTS WITH COVID-19 AND ITS IMPACT ON THE COURSE OF THE ACUTE INFECTION AND POST-COVID PERIOD

Alexander Arutyunov1,2, Marina Trubnikova3, Gregory Arutyunov4, Mikhail Batyushin5, Ekaterina Tarlovskaya6, Roman Bashkinov5, Evgenii Melnikov7, Tatiana Batluk8 and Elizaveta Gordeychuk4

1National Institute of Health after academician S. Avdalbekyan, Erevan, Armenia, 2Eurasian Association of Internal Medicine, “ACTIV SARS-CoV-2” Working Group, Erevan, Armenia, 3Eurasian Association of Internal Medicine, “ACTIV SARS-CoV-2” Working Group, Sochi, Russia, 4Eurasian Association of Internal Medicine, “ACTIV SARS-CoV-2” Working Group, Moscow, Russia, 5Eurasian Association of Internal Medicine, “ACTIV SARS-CoV-2” Working Group, Rostov-on-Don, Russia, 6Eurasian Association of Internal Medicine, “ACTIV SARS-CoV-2” Working Group, Nizhny Novgorod, Russia and 7Eurasian Association of Internal Medicine, “ACTIV SARS-CoV-2” Working Group, Saint Petersburg, Russia

Background and Aims: It is known that SARS-CoV-2 virus infection can contribute to kidney damage. In the literature, the incidence of acute kidney injury (AKI) during the acute period of COVID-19 is estimated to range from 5 to 36.6%. This complication significantly aggravates the course of both the acute phase and post-COVID period. However, the number of studies investigating these interactions is currently insufficient. To determine the incidence of AKI in the acute phase of COVID-19 and to assess the impact of this complication on the post-COVID period.

Method: The international register “Dynamics analysis of comorbidities in SAES-CoV-2 survivors” (“ACTIV”) (NCT04492384) was established to assess the course of COVID-19 in the Eurasian region and involved specialists from 7 countries. ACTIV is a multicenter, non-interventional, real-world clinical practice register that included men and women over 18 years of age with a confirmed diagnosis of COVID-19. The analysis included 9206 patients with reported evidence of kidney damage or its absence. In the register, the presence of AKI was determined from the attending physician’s notes in the medical records (according to modern diagnostic criteria) and the difference in serum creatinine levels $\geq 26.5 \mu mol/l$ during inpatient treatment for COVID-19. The post-COVID period was analyzed using telephone surveys of 3099 patients at 3 months, 2493 patients at 6 months and 1782 patients, at 12 months after recovery from COVID-19.

Results: AKI was detected in 11.6% (n = 1068) of cases during the inpatient treatment of the acute SARS-CoV-2 infection. Among markers of severe infection, AKI was more common (p < 0.001) than cytokine storm (7.46% of patients) or sepsis (0.17% of patients). Analysis showed that AKI occurred in patients with higher average body mass index (BMI) (29.6 kg/m² (25.1; 33.5) vs. 27.8 kg/m² (24.8; 31.6) without AKI, p = 0.018) and serum glucose levels (6.0 (5.2; 8.55) mmol/l vs. (5.8 (5.0; 7.0) mmol/l without AKI, p = 0.011). AKI increased the odds of death in the acute period of COVID-19 by 3.94 times (95% confidence interval (CI) 3.24–4.78; p = 0.0001). Similar results were recorded 3 months after recovery (Table 1).

Conclusion: AKI was reported in 11.6% of patients with COVID-19 who were hospitalized for treatment of acute infection. Kidney damage occurred in patients with higher BMI and serum glucose levels. Patients with AKI during SARS-CoV-2 infection had a significantly higher risk of death in the first 3 months after recovery.
Table 1: Analysis of the probability of death within 12 months after recovery from SARS-CoV-2, depending on the presence/absence of AKI in the acute phase of infection.

INCIDENCE AND PREDICTORS OF MAJOR ADVERSE KIDNEY EVENTS IN ICU PATIENTS WITH SEPSIS: A PROSPECTIVE COHORT STUDY FROM A DEVELOPING COUNTRY

Indu Ramachandra Rao, Saurabh Thanekar, Shankar Prasad Nagaraju and Ravindra Attur Prabhu

Kasturba Medical College, Manipal, Manipal Academy of Higher Education, Manipal, Karnataka, India, Department of Nephrology, India

Background and Aims: Acute kidney injury (AKI) occurs in 15-60% of intensive care unit (ICU) admissions and is associated with higher mortality, morbidity and increased healthcare costs. Major adverse kidney events (MAKE) is a clinically meaningful patient-centred outcome for AKI which includes mortality, need for renal replacement (RRT) and persistent kidney dysfunction. There is a paucity of data on the incidence and risk factors of MAKE, particularly from developing countries. We sought to examine the incidence of MAKE at day 30 (MAKE30) and its predictors in a cohort of critically ill patients with sepsis.

Method: This was a prospective cohort study conducted in the medical ICUs of a tertiary-care hospital in India. Ethical clearance was obtained from the Institutional Ethics Committee. Adult patients (≥ 18 years) admitted in the medical ICUs between 1st September, 2022 and 31st December, 2022 with sepsis (as defined by Sepsis-3 criteria) were included. Those with chronic kidney disease stage 5/5D, those requiring dialysis within 72 hours of admission and with an ICU stay of <72 hours were excluded. Baseline clinical and demographic data were recorded on the day of admission. AKI was defined as per KDIGO 2012 guidelines. Patients were followed up till hospital discharge or day 30 (whichever was earlier) and clinical outcomes were noted. The primary outcome measure was MAKE30 (defined as a composite of death, provision of RRT, or sustained loss of kidney function i.e., a final inpatient creatinine ≥200% of the baseline value, at hospital discharge or at 30 days, whichever comes first).

Results: A total of 250 patients admitted in the medical ICUs during the study period were included for analysis. The baseline characteristics are tabulated below (Table 1). Over the 30-day follow-up period, AKI was noted in 185 (74%) patients, with stage 1 AKI in 38 (15.2%), stage 2 AKI in 29 (11.6%) and stage 3 AKI in 118 (47.2%). Renal replacement therapy was initiated in 86 (34.4%) patients. Mortality occurred in 58 (23.2%). Overall, MAKE30 was seen in 102 (40.8%) patients. Serum lactate (OR 1.04, 95% CI:1.01-1.06; P = 0.010) and SOFA score (OR 1.38, 95% CI:1.27-1.56; P <0.001) at admission were independently associated with MAKE30 (Table 2). There was no association with age, gender, diabetes, type of resuscitation fluid or cumulative fluid balance (at 72 hours) with MAKE30.

Conclusion: In this cohort of critically ill patients with sepsis, MAKE30 was observed in 40.8%. Serum lactate and SOFA score at admission were independent predictors of MAKE30.

Abstracts i1099

Division of Nephrology, Guangzhou, P.R. China

National Clinical Research Center for Kidney Disease, State Key Laboratory of Organ Failure Research, Nanfang Hospital, Southern Medical University, Division of Nephrology, Guangzhou, P.R. China

Background and Aims: Antiviral therapy is commonly used to treat herpes zoster. Though antivirals are generally considered nephrotoxic, few studies compared the relative risk of acute kidney injury in patients with herpes zoster that is attributable to different antivirals. We aim to examine the association of use of different antivirals with hospital-acquired acute kidney injury (HA-AKI) among Chinese adults with herpes zoster.

Method: The study population was derived from the China Renal disease System (CRDS), a retrospective cohort of hospitalized patients from 19 medical centers throughout China. We selected from CRDS 3,847 adults who received antiviral therapy for herpes zoster during hospitalization. We identify and stage AKI using patient-level serum creatinine data according to the Kidney Disease Improving Global Outcomes (KDIGO) criteria. We compared the relative risks of HA-AKI among patients treated with different antivirals using Cox proportional hazards model, and explored the non-linear association between the accumulative dose of antivirals and the risk of HA-AKI using a penalized smoothing spline.

Result: Among 3,847 patients, 1,585 (41.2%), 699 (18.2%), 599 (15.6%) and 964 (25.1%) were treated with acyclovir/valacyclovir, ganciclovir, penciclovir/famciclovir, and fosacarnet, respectively. The incidence of HA-AKI was 4.9%, 2.9%, 2.8% and 0.8%, respectively, in the patients treated with acyclovir/valacyclovir, ganciclovir, penciclovir/famciclovir, and fosacarnet. Compared with acyclovir/valacyclovir therapy, use of foscarnet was associated with a 69% reduction in the risk of HA-AKI (hazard ratio [HR], 0.31; 95% CI, 0.14-0.66), while use of other nucleoside analogues was associated with a marginally lower risk of HA-AKI, with a HR (95% CI) of 0.31 (0.14-0.68). The incidence of HA-AKI was 4.9%, 2.9%, 2.8% and 0.8% in the patients treated with acyclovir/valacyclovir, ganciclovir, penciclovir/valamivucir, and fosacarnet, respectively. The incidence of HA-AKI was 4.9%, 2.9%, 2.8% and 0.8%, respectively, in the patients treated with acyclovir/valacyclovir, ganciclovir, penciclovir/famciclovir, and fosacarnet.

Conclusion: Antiviral therapies for herpes zoster, acyclovir/valacyclovir was associated with the highest relative risk of HA-AKI, and the association appears to be dose dependent. Clinicians should exercise rational drug use according to the different renal toxicity associated with a particular antiviral drug.

#4815

COMPARISON OF DIFFERENT ANTIVIRALS REGARDING THEIR ASSOCIATION WITH HOSPITAL-ACQUIRED ACUTE KIDNEY INJURY AMONG ADULTS WITH HERPES ZOSTER

Ruqi Xu, Xu Xin and Sheng Nie

National Clinical Research Center for Kidney Disease, State Key Laboratory of Organ Failure Research, Nanfang Hospital, Southern Medical University, Division of Nephrology, Guangzhou, P.R. China

Background and Aims: Antiviral therapy is commonly used to treat herpes zoster. Though antivirals are generally considered nephrotoxic, few studies compared the relative risk of acute kidney injury in patients with herpes zoster that is attributable to different antivirals. We aim to examine the association of use of different antivirals with hospital-acquired acute kidney injury (HA-AKI) among Chinese adults with herpes zoster.

Method: The study population was derived from the China Renal disease System (CRDS), a retrospective cohort of hospitalized patients from 19 medical centers throughout China. We selected from CRDS 3,847 adults who received antiviral therapy for herpes zoster during hospitalization. We identify and stage AKI using patient-level serum creatinine data according to the Kidney Disease Improving Global Outcomes (KDIGO) criteria. We compared the relative risks of HA-AKI among patients treated with different antivirals using Cox proportional hazards model, and explored the non-linear association between the accumulative dose of antivirals and the risk of HA-AKI using a penalized smoothing spline.

Result: Among 3,847 patients, 1,585 (41.2%), 699 (18.2%), 599 (15.6%) and 964 (25.1%) were treated with acyclovir/valacyclovir, ganciclovir, penciclovir/famciclovir, and fosacarnet, respectively. The incidence of HA-AKI was 4.9%, 2.9%, 2.8% and 0.8%, respectively, in the patients treated with acyclovir/valacyclovir, ganciclovir, penciclovir/valamivucir, and fosacarnet. Compared with acyclovir/valacyclovir therapy, use of foscarnet was associated with a 69% reduction in the risk of HA-AKI (hazard ratio [HR], 0.31; 95% CI, 0.14-0.68), while use of other nucleoside analogues was associated with a marginally lower risk of HA-AKI, with a HR (95% CI) of 0.31 (0.14-0.68). The incidence of HA-AKI was 4.9%, 2.9%, 2.8% and 0.8% in the patients treated with acyclovir/valacyclovir, ganciclovir, penciclovir/famciclovir, and fosacarnet. When compared with foscarnet, nucleoside analogues (HR, 2.72; 95% CI, 1.28-5.75) showed a higher risk of HA-AKI. The associations were consistent across various subgroups and sensitivity analysis.

Conclusion: Antiviral therapies for herpes zoster, acyclovir/valacyclovir was associated with the highest relative risk of HA-AKI, and the association appears to be dose dependent. Clinicians should exercise rational drug use according to the different renal toxicity associated with a particular antiviral drug.
The age of our patients varied between 24 and 64 years for an average of 42 years. The male sex was predominant (78.57%) 11 men versus 3 women with no history of previous kidney disease. The average hospital stay was 20 days [12-42 days]. The most common clinical signs were oligo-anuria (85.7%), abdominal pain (57.1%), nausea and vomiting (42.8%), flank pain (42.8%) and muscle pain (14.2%), hypertension in 5 patients (35.7%), while 4 were hypotensive. The average creatinine on admission was 22mg/l [14-42.3], the average CPK level was 6240UI/L [2225-12570], the myoglobin was assayed in a single patient which returned on admission was 22mg/l [14-42.3], the average CPK level was 6240UI/L [2225-12570], the myoglobin was assayed in a single patient which returned.

1 HR: hazard ratio.
2 Acyclovir/valacyclovir, penciclovir/famiclovir, and ganciclovir were combined as one group, given that we found no statistically significant differences in the risk of HA-AKI between nucleotide analogues.

Cox model was adjusted for age, gender, co-morbidities, mechanical ventilation, ICU admission, other nephrotoxic drugs and operations.

**NON TRAUMATIC RHABDOMYOLYSIS AND ACUTE RENAL FAILURE: WHICH INDICATIONS OF RENAL REPLACEMENT THERAPY?**

Zineb Aboudar, Sara Masrour, Mariam Chettati, Wafaa Fadili and Inass Laouad

Centre Hospitalo-Universitaire Mohammed VI Marrakech, Marrakech, Morocco

**Background and Aims:** The aim of our study is to identify the causes of non-traumatic rhabdomyolysis in our context, to study the clinical and biological presentation of patients and the indications of renal replacement therapy in the management of this entity.

**Method:** Our study is a monocentric retrospective study conducted at the university hospital Mohamed VI of Marrakech including 14 patients who presented rhabdomyolysis complicated by acute kidney injury (AKI) with no traumatic context. Those patients were followed up at intensive care unit and nephrology department over a period of 10 months from March to December 2022.

**Results:** The age of our patients varied between 24 and 64 years for an average of 42 years. The male sex was predominant (78.57%) 11 men versus 3 women with no history of previous kidney disease. The average hospital stay was 20 days [12-42 days]. The most common clinical signs were oligo-anuria (85.7%), abdominal pain (57.1%), nausea and vomiting (42.8%), flank pain (42.8%) and muscle pain (14.2%), hypertension in 5 patients (35.7%), while 4 were hypotensive. The average creatinine on admission was 22mg/l [14-42.3], the average CPK level was 6240UI/L [2225-12570], the myoglobin was assayed in a single patient which returned on admission was 22mg/l [14-42.3], the average CPK level was 6240UI/L [2225-12570], the myoglobin was assayed in a single patient which returned.

**Conclusion:** The management of non traumatic rhabdomyolysis is based above all on rehydration in order to establish blood volume and eliminate the myoglobin pigment. The use of RRT is necessary in some cases such as severe acute renal failure, threatening hyperkalaemia, acidosis or persistent anuria. Several studies suggest the benefit of its early initiation, which still remains to be demonstrated.

**A STUDY FOR HOSPITALIZED PATIENTS WITH COVID-19 WITH/WITHOUT IMMUNOSUPPRESSION AND RENAL FAILURE: DOES THE SURVIVAL RATE CHANGE?**

Styliani Vakiani1, Maria Triantafyllidou2, Dimitris Katsanos3, Klaoudia Lakoniti3 and Panteleimon Vakianis3

1 General Hospital of Corfu, Nephrology, Corfu, Greece, 2Corfu Gen Hosp, Nephrology, Corfu, Greece and 3Corfu Gen Hosp, ICU DEP, Corfu, Greece

**Background and Aims:** Introduction The purpose of our research topic was to study the survival of immunocompromised or non-immunosuppressed patients as well as patients with Chronic Kidney Disease who were hospitalized due to covid-19 infection during a two-year period (2020-2022).

**Method:** Material and Methods A total of 1270 patients (of whom 570 were women) with a mean age of 63 years (+/- 24 years) were studied. From these, 1000 patients were without immunosuppression and 270 were theoretically and practically immunosuppressed, including 30 patients with Chronic Kidney Disease and of these 10 were with end-stage Chronic Kidney Disease. It is important to mention that 87 patients had to be hospitalized in the ICU, of which 74 died. The rest were hospitalized in the Bioccontainment Unit, where

**UTILITY OF RENAL BIOPSY IN THE ETOLOGY, MANAGEMENT AND OUTCOME OF POSTPARTUM ACUTE KIDNEY INJURY**

Manoj Jain¹, Dharmander Bhadauria², Narayan Prasad² and Anupma Kaul²

¹Sanjay Gandhi Postgraduate Institute of Medical Sciences, Department of Pathology, Lucknow, India and ²Sanjay Gandhi Postgraduate Institute of Medical Sciences, Department of Nephrology, Lucknow, India

**Background and Aims:** Acute kidney injury (AKI) is a serious complication during pregnancy and postpartum period resulting in significant maternal morbidity, mortality and fetal loss. Pregnancy related acute kidney injury is still more prevalent in developing countries. This study aims to evaluate renal biopsies in postpartum period AKI (PPAKI) with etiology and its management and outcome.

**Method:** Retrospective analysis of 83 native renal biopsies received in the department of pathology, SGPGIMS, Lucknow, a tertiary care center in India with PPAKI from January 2007 to December 2021 were analyzed. Clinical and laboratory data were retrieved and renal biopsy histology slides were reviewed.

**Results:** Eighty-three patients with mean age 27.5±4.6 years had biopsy proven PPAKI. Cesarean section, vaginal delivery, hysterectomy and abortion were performed in 51, 19, 2 and 11 patients respectively. The cause of AKI was sepsis (38.6%), postpartum hemorrhage (26.5%), thrombotic microangiopathy (TMA) (11%), pre-eclampsia (3.7%) and other (20%). Duration of onset of AKI after delivery/abortion ranged from 0 to 30 days (mean 4.5±6.3 days). Fetal loss was seen in 31.7% patients. Biopsy showed partial/complete renal cortical necrosis (56.6%), TMA (24.1%), acute tubular injury (ATI) (4.8%), Lupus nephritis flare in 3.6% and other glomerular diseases (8.4%) and Tubulointerstitial nephritis in (1.2%) patient. All received multiple sessions of haemodialysis and 10 patients also had plasmapheresis. During hospital stay one died due to sepsis and shock, remainder were discharged in a stable condition with complete recovery in (5), partially recovery in (7); and 61 (71%) patients required continued renal replacement therapy. Two patients died and two had subsequent live related renal transplantation had a follow up follow-up.

**Conclusion:** AKI is a serious complication in postpartum period and require early and prompt attention to reduce fetal and maternal morbidity. Sepsis is the commonest cause of postpartum AKI.

**IMPROVING THE DIAGNOSIS OF MYOCARDIAL INFARCTION IN CHRONIC KIDNEY DISEASE**

Marrica Mcdonald-Coley and Marilyn Lawrence-Wright

University of the West Indies, The Department of Medicine, Kingston 7, Jamaica

**Background and Aims:** Chronic Kidney Disease has significant morbidity and mortality owing to the increased prevalence in cardiovascular disease. This increase in morbidity and mortality is seen more so as glomerular filtration rate (GFR) declines, that is, advanced kidney failure with GFR equal to or less than 30ml/min/1.73m². Hence, it is important to control risk factors and accurately diagnose myocardial infarction in this cohort of patients.

**Secondary objectives showed that social isolation was significantly associated with confirmed myocardial infarction. Additionally, ST changes, and T-QRS discordance on electrocardiogram were found more commonly in the myocardial infarction group. Other diagnostic tools such as angiography proved to be an underutilized investigation with a prevalence of 13% in the kidney disease cohort at the University of the West Indies during the years 2018 to 2020.**

**Method:** In this retrospective cross-sectional study, data was collected from the hospital records system at the University of the West Indies. Patients with an admission diagnosis of acute coronary syndrome, unstable angina, non-ST elevation myocardial infarction, ST elevation myocardial infarction and chronic kidney disease were included in the study population. Cases were assigned based on whether or not myocardial infarction was confirmed on echocardiogram.

**Results:** Of the total number of 102 cases, 58 were chosen based on fulfillment of diagnostic criteria. 13 (22.4%) had echocardiographic evidence of a new myocardial infarction while 44 (75.9%) had no echocardiographic evidence of new myocardial infarction. Receiver Operator Characteristic Curves (ROC) used to evaluate the diagnostic performance of high sensitivity cardiac troponin T and interval/ delta changes showed an ideal value 141.50ng/L on first troponin T and 100.75ng/L on serial troponin T with delta change of 20.5% (sensitivities of 61.5%, 72.7% and 72.7% respectively). Area under the Receiver-Operating Characteristic Curve (AUC) used to determine the diagnostic accuracy of the highly sensitivity cardiac troponin T and interval delta change demonstrated high accuracy of 0.708 for the first troponin T; 0.750 for the second troponin T and 0.767 for the interval or delta change.

**Conclusion:** Overall, we showed that serial troponin measurements in kidney disease patients increase sensitivity for predicting myocardial infarction and that the values are nearly 10 times that used for the general population. An interval change of 20.5% was also predictive of myocardial infarction.
THE ROLE OF EARLY ACUTE KIDNEY REPLACEMENT THERAPY (AKRT) IN THE PROGNOSIS OF PATIENTS WITH COVID-19: A RANDOMIZED CLINICAL TRIAL

Paula Gabriela Sousa de Oliveira, Lais Gabriela Yokota, Welder Zamoner, Andre Balbi and Daniela Ponce

São Paulo State University (Unesp), Medical School, Botucatu, Brazil

Background and Aims: The COVID-19 pandemic has increased the burden of morbidity and mortality worldwide and in its moderate to severe forms is associated with serious complications such as Acute Kidney Injury (AKI). AKI related to COVID-19 appears to be multifactorial and the AKI incidence is around 20%, with the need for dialysis in up to 40-50% of critically ill patients. So far, there has been no evidence of benefit from early dialysis in different contexts of AKI. In the context of COVID-19 it is possible that the indication of early dialysis support can help and improve outcomes with inflammation and volume control. The objective of the study was to evaluate the role of early acute kidney replacement therapy (AKRT) in the context of COVID-19.

Method: We analyzed 108 patients from a randomized open-label clinical trial with AKI 3 according to the KDIGO 2012 criteria, with severe acute respiratory syndrome with confirmed COVID-19 (RT-PCR technique or serology), admitted from March 2020 to May 2021 in a reference public hospital in the State of São Paulo (Brazil). Patients were randomized to early AKRT indication (either cytokine storm or fluid balance cumulative greater than 3% of body weight) or standard indication (classic indications or systemic demand and renal capacity imbalance). Cytokine storm was characterized as uninterrupted fever (38°C or more) for at least 12 hours and exclusion criteria were patients younger than 18 years, pregnant women, chronic kidney disease (CKD) stages 4 and 5, kidney transplant recipients. Patients were randomized in blocks for allocation to groups and the primary outcome was hospital mortality. The study was approved by the research ethics committee, registered in the Brazilian Clinical Trials Registry. Seeking a detection of a 20% mortality difference between the standard and early groups, the required sample size would be 48 patients per group and was assumed an alpha error of 5%. All analyses were performed using SPSS 28.0.1.1 (15).

Results: 108 patients were included in the intention-to-treat analyses (41 in the early group and 67 in the standard group). 66.7% were men, 86.9% white, mean age of 62.56 ± 14.25 years, 93.9% in intensive care unit, 100% in mechanical ventilation (MV) and 93.5% in use of vasoactive drugs. The most common comorbidities were hypertension (68.5%), diabetes (39.8%) and obesity (52.8%). Hematiauria (47.9%) and proteinuria (74.7%) were common. The P/F ratio. ATN-SS e APACHE II scores were mean, respectively, 145.40 ± 67.70; 0.75 ± 0.12 ± 20.04 ± 6.64. 51.9% of the sample had a cytokine storm and the overall mortality was 87%. The standard and early groups were similar in gender, race, comorbidities, severity, medications, and laboratory markers of severity as well as catheter site, system coagulation, number of dialysis sessions and mortality (63.8% in the standard vs 36.2% in the early, p = 0.32). There was a difference in age e modality of dialysis between the groups (higher mean of age (57.78±14.24 years vs 65.49±13.54) and more continuous dialysis (66.7% vs 33.3%, p < 0.01) in the early group. Hypertension (68.9% vs 31.1%, p = 0.051), CKD (80% vs 20% p = 0.038) and dlysidipemia (80.8% vs 19.2%, p = 0.52) were more common in the standard. The early group had a longer ICU stay (20.26±20.93 days vs 13.22±11.34, p = 0.053), lower maximum creatinine (3.88±1.88 vs 5.24±2.46, p = 0.004) and lower ATN-SS (0.72 ±0.12 vs 0.78±0.12, p = 0.017). In the survival analysis, a better hospital survival trend was observed in the early group, but with no statistically significant difference (p = 0.061). Use of angiotensin converting enzyme inhibitor (ACEI), 42.9% vs 13.8, p = 0.008, and longer time in MV (28.71±12.48 days vs 13.42±13.99, p = 0.001) were associated with longer mortality. In the logistic regression, use of ACEI (OR 0.007, 95% CI 0-0.29, p = 0.009), MV time (OR 0.93, 95% CI 0.88-0.99, p = 0.023) and higher APACHE II (OR 1.28, 95%CI 1.02-1.6, p = 0.03) were associated with mortality.

Conclusion: It was observed that the use of ACEI, longer ventilation time and APACHE II score were associated with mortality, while early AKRT indication had no impact in survival of patients.
Background and Aims: At least 30% of acute kidney injury (AKI) survivors lack appropriate follow up after hospital discharge. AKI survivors have highly dynamic posthospital course which warrants close monitoring to prevent adverse outcomes. Digital health solutions like remote patient monitoring (RPM) could be used to improve quality and efficiency of AKI survivor care. The purpose for this study was to assess the feasibility and effectiveness of the Mayo Clinic AKI RPM program, launched in October 2021.

Method: The Mayo Clinic AKI RPM program enrolled individuals who experienced AKI during a hospitalization and underwent nephrology consultation (Figure 1). Feasibility was assessed as the proportion of individuals approached for AKI RPM enrollment during the first year of the program who submitted at least one set of vitals after discharge. An effectiveness analysis compared stage 3 AKI survivors enrolled in AKI RPM with at least 30-days of follow-up to matched historical controls (3:1) sampled from before RPM was available (2018-2021). The primary endpoint was hospital readmission or emergency department (ED) visit within 30-days, assessed with the Chi-square test. Secondarily we explored time to first readmission or ED visit with a Kaplan-Meier survival curve with a non-parametric comparison between groups, as well as readmission length of stay with the Wilcoxon Rank Sum test due to right skewed data distribution.

Results: Of the 50 individuals approached for AKI RPM participation, 45 (90%) submitted at least one set of vitals. Among AKI RPM patients, 34 patients with stage 3 AKI were matched to 102 controls based on baseline characteristics and demographics. Dialysis during hospitalization (liberated by discharge) was used in 36 (27%) of patients. Sixty (44%) individuals required ICU level of care. Median (IQR) discharge estimated glomerular filtration rate was 15 (11, 27) mL/min/1.73m². Through matching, groups were well balanced with respect to pertinent baseline demographics. Hospital readmission or ED visit occurred in 17 (50%) of AKI RPM patients within 30-days compared to 39 (38%) of controls within 30-days ($P = .23$). The endpoint appeared driven by ED visits within 30-days, not readmissions [At least one ED visit: 13 (38%) vs 21 (21%), respectively ($P = .04$); At least one hospital readmission: 7 (21%) vs 26 (26%), respectively ($P = .56$)]. Time to first readmission or ED visit within 30-days was similar between groups ($P = .35$; Figure 2). Among the 33 patients who were readmitted to the hospital within 30-days, readmission length of stay was similar in the AKI RPM group compared to controls [Median (IQR) 76 (10.6, 121) hours vs 108 (70, 165) hours; $P = 0.33$].

Conclusion: In conclusion, AKI RPM was a feasible program when used to bridge the care continuum (hospital to home) in non-dialysis dependent AKI survivors. Incidence of at least one hospital readmission or ED visit within 30-days was statistically similar between AKI RPM patients and controls. More AKI RPM patients experienced ED encounters in the 30-days after discharge, but frequency of hospital readmission was similar. Digital health solutions such as RPM offer a unique opportunity to address the important gap in AKI care after discharging from the hospital. Additional research is needed to explore the impact of AKI RPM on patient outcomes.

Figure 1: AKI RPM algorithm for escalation of care based on laboratory and patient-provided data. RPM nurses review data daily and call patients at a minimum once weekly. If a patient has a parameter that meets emergent criteria, they are directed to the ED. Urgent criteria are referred directly to the nephrology provider. Patients who meet routine or semi-urgent criteria are monitored by RPM nurses in collaboration with specialty nurses.
Objective: To compare different vancomycin administration protocols to assess serum concentrations and area under the curve/minimum inhibitory concentration (AUC/MIC) ratio from PK/PD.

Methods Randomized, non-blind clinical trial, including critically ill adults diagnosed with septic AKI on conventional (4 hours) and prolonged HD (6 and 10 hours) and using vancomycin for at least 72 hours from May/2019 to May 2021. Sessions of patients were analyzed and randomized into three groups (G): G control (C, dose of 15 mg/kg after HD session), G intervention (I) 2 hours (dose of 7.5 mg/kg in the second hour of HD and 7.5 mg/kg after the session) and IG continuous infusion (dose of 30 mg/kg in continuous infusion pump, in 24 hours). Patients on chronic dialysis, pregnant women, and those whose session was interrupted for clinical or technical reasons were excluded.

Results Of the 316 patients recruited, 87 were randomized, and 174 HD sessions were monitored. There was a predominance of males (69.5%), age 61±11 years, APACHE II 31±6, ATN-SS 0.79±0.14. For the analysis, 28 sessions belonged to the CG, 47 sessions to the 2-hour IG, and 31 to the continuous infusion IG. The groups were similar in age, weight, comorbidities, severity scores, use of diuretics and nephrotoxic drugs, urine output, albumin, CRP, hematocrit, HD modality, recovery of renal function, and death. When HD sessions were analyzed, there was no difference between the groups regarding Kt/V, ultrafiltration, system coagulation, or hypotension. The CG had a higher frequency of subtherapeutic serum levels at the end of HD compared to the 2-hour IG and continuous infusion (86.7% vs. 42.2% vs. 3.2%, p < .0001), higher clearance dialysis (p = .04) and lower AUC/MIC (p < .0001). The IG continuous infusion had a higher frequency of supratherapeutic concentrations (71%). Logistic regression identified the initial concentration variable as a risk factor (OR 1.16, p = .001) for a non-therapeutic concentration (AUC/MIC less than 400 mg·h/L or greater than 600 mg·h/L) of vancomycin. In contrast, the 2-hour intervention group was identified as a protective factor (OR 0.24, p = .04).

Conclusion: Our results suggest that administering vancomycin during dialysis resulted in a lower proportion of supratherapeutic or subtherapeutic concentrations compared to administration in continuous infusion or after the end of the session, respectively. New studies are needed to suggest more appropriate doses and assess these findings’ impact on clinical outcomes.
DIURETIC RESISTANCE PREDICTORS IN ACUTE DECOMPENSATED HEART FAILURE ADMISSIONS: A BROADER LOOK

Alina Mabel Martín1, Pablo Klin2, Rodrigo Esparza Iraola3 and Pablo Rafaelle4

1Fundación Favaloro - Edificio Central, Nephrology, Dialysis and Renal Transplantation Unit, Buenos Aires, Argentina; 2Fundación Favaloro - Edificio Central, Intensive Care Telemetry Unit, Buenos Aires, Argentina and 3Fundación Favaloro - Edificio Central, Cardiology resident, Buenos Aires, Argentina

Background and Aims: Failing to relieve congestion portends a rise in mortality rate and length of stay in acute decompensated heart failure (ADHF) hospitalizations. That situation corresponds to diuretic resistance (RDIUR). We sought to evaluate clinical and biochemical predictors of RDIUR, including those non-conventional ones we noticed as relevant in prognosis in our clinical practice.

Method: We conducted an observational, analytical and cross-sectional study, with prospective and consecutive patient (P) data acquisition. We included P over 18 years-old, who were admitted to the Intensive Care Telemetry Unit in our Hospital in the period between July; 2011 and May, 2022 due to ADHF diagnosis. All P received diuretic IV therapy as part of pharmacological treatment. As mentioned in earlier presentations, urine output (UO) was registered in all P and failure to achieve an UO ≥ 1.5 ml/kg/hour under a pre-established protocol that included and initial 100 mg of IV furosemide bolus followed by 2 a hours of a 3 mg/hour furosemide continuous infusion. Under failure to achieve the goal, furosemide dose was doubled for two additional hours. Failure to respond to this strategy was called “diuretic resistance”. P who received a heart transplant during index admission or those who were on chronic dialysis were excluded from this study. Clinical, epidemiological and biochemical variables were registered. Missing data was imputed by means of multiple regression with chained equations. We constructed a multivariate logistic regression, with selection of relevant predictors completed by resampling and regularization of a Lasso regression model. Statistical significance was considered with a 5% of alpha error. Analysis was conducted using R (R Core Team, 2021), with RStudio (RStudio Team, 2020) as Integrated Development Environment for R, and the tidymodels package (Silge and Kuhn, 2022).

Results: A total of 1359 P were included. RDIUR was observed in 177 P (13%). These P were younger (69 years old vs 72 p = 0.02), with a higher prevalence of diabetes (39.5% vs 28%; p = 0.002), admission creatinine levels (1.4 vs 1.1 mg/dl; p < 0.001), lower total T3 serum levels (0.56 mg/ml vs 0.7; p < 0.001), with higher incidence of cholestasis (61 vs 40%; p < 0.001), and anasarca as clinical phenotype of systemic congestion (17.5% vs 8.5% p < 0.001). In-hospital mortality was higher in P who developed RDIUR (32.8 vs 16, p < 0.001), worsening heart failure (48% vs 11; p < 0.001), and furosemide dose at 2nd admission day (175.4 vs 123.4 p < 0.001) were higher in these P. We found no differences in left ventricular ejection fraction (38 vs 41 p = 0.21), first day natriuresis (75.5 vs 78.4; p = 0.093), coronary etiology vs others (20% vs 22; p = 0.26) or one month readmission rate (33% vs 37; p = 0.27). In the adjusted model, instotropic support (OR 5.2; IC95% 3.4-8; p < 0.001), worsening heart failure (OR 3.4; IC95% 2.2-5.3; p < 0.001), furosemide dose at 2nd day (OR 1, IC95%; P 0.001), admission creatininemia (OR 2.05; IC95% 1.7-2.6; p < 0.001), anasarca phenotype (OR 2.3; IC95% 1.4-3.9; p = 0.002) and normal T3 levels (OR 0.05; IC95% 0.02-0.14; p < 0.001) were identified as independent predictors of RDIUR development. Model accuracy was 0.89 and ROC-AUC 0.87. In the same way, RDIUR (OR 2.57; IC95% 1.5-4.3; p < 0.001), worsening heart failure (OR 4.1 IC95% 2.4-7; p < 0.001), instotropic support (OR 3; IC95% 1.7-5.2; p < 0.001) and cholestasis (OR 3.1; IC95% 1.9-5.2; p < 0.001) were found as independent predictors of in-hospital mortality.

Conclusion: Diuretic resistance is a serious event in patients hospitalized for ADHF, and considerably associated with mortality. A decreased renal reserve, low T3 levels, and anasarca at admission were significantly associated with diuretic resistance development. Considering “new” biochemical predictors as admission T3 levels might add strength to this subset of patients, opposed to information displayed by “classical” event predictors in ADHF patients, as ventricular function or etiology of cardiac disease. Due to clinical potential implications these observational results should be confirmed under evidence based protocols.

Pregnancy Related Acute kidney injury (PR-AKI) is a global health problem with substantial maternal and fetal morbidity and mortality. Late referral, and late diagnosis of women with risks of PR-AKI represent the major barriers for curtailment of this ugly trend, particularly in the developing world. Our past experience per se revealed striking maternal and fetal mortality of women with PR-AKI. Great strides are strongly needed to save maternal and fetal lives. This study assessed the impact of implementing an innovative obstetric nephrology service (ONS) and healthcare program on maternal and fetal outcomes in women at risk of PR-AKI.

Method: An innovative interdisciplinary obstetric nephrology clinic was established in 2020 to improve the quality of care for pregnant women at risk of PR-AKI. The service was staffed by both nephrologists and obstetricians. Women who presented to the clinic were stratified into low, moderate, and high-risk groups. A risk stratification-based care program was adopted. Very high-risk women were admitted to the maternal care unit. The study compared the outcomes of ONS-treated women who completed their follow up (n = 43) versus two groups of conventionally treated women (n = 40) and women presented before service (n = 40).

Results: Although they had greater pre-existing risks, ONS-treated women had no reported maternal or fetal mortality compared to women in the conventionally treated group (11.8% and 51.5% respectively), and to women presented before service (22.5% and 45% respectively). Progression to end-stage renal disease was significantly less in ONS-treated women compared to both conventionally treated and those treated before service (3% versus 13.2% and 37.5% respectively).

Conclusion: Easily feasible Obstetric nephrology service implementation and adoption of early referral program and diagnosis policies were associated with better maternal and fetal survival as well as better renal outcomes. Provision of parallel services is strongly recommended to decrease the magnitude of PR-AKI.

IMPACT OF ALBUMIN BINDING FUNCTION ON PHARMACOKINETICS AND PHARMACODYNAMICS OF FUROSEMIDE

Gerd Klinkmann¹, Sebastian Klammt², Daniel Reuter¹ and Steffen Mitzner²

¹University Medical Center Rostock, Department of Anaesthesiology, Intensive Care Medicine and Pain Therapy, Rostock, Germany and ²University Medical Center Rostock, Department of Internal Medicine, Division of Nephrology, Rostock, Germany

Background and Aims: Albumin binding of furosemide forms the basis for its transport to the kidney and subsequent tubular secretion, which is a prerequisite for the effect of furosemide. Accordingly, high albumin concentrations should result in higher efficacy of furosemide. However, study results on the combination of furosemide in conjunction with albumin and on the efficacy of furosemide in hypoalbuminemia did not confirm this hypothesis. The aim of this study was to determine the efficacy of furosemide not only in relation to concentration, but also to take albumin function into account.

Method: In a prospective and non-interventional clinical observational trial, blood and urine samples from 50 intensive care patients receiving continuous intravenous furosemide therapy were evaluated. Albumin binding capacity (ABiC) determination allowed conclusions to be drawn about the binding site-specific loading state of albumin by quantifying the unbound fraction of furosemide.
the fluorescent marker dansylsarcosine. In addition, assessment of the total concentration of furosemide in plasma and urine as well as the concentration of free furosemide fraction in plasma was performed by HPLC-MS. The efficacy of furosemide was evaluated by the ratio of urine excretion to fluid intake.

**Results:** In patients with an ABiC ≥ 60% free furosemide fraction was significantly lower compared to patients with a lower ABiC (p < 0.001), urinary furosemide concentration was higher (p = 0.136), and a significantly higher proportion of infused furosemide was excreted renally (p = 0.010). ABiC was positively correlated (r = 0.908, p = 0.017) with the increase in urine excretion to fluid input ratio after initiation of furosemide therapy.

**Conclusion:** ABiC could serve as a marker for individual response to furosemide and could be used to generate patient-specific therapeutic regimens. In view of the relatively low number of patients in this study, the relationship between furosemide efficacy and albumin function should be investigated in larger studies in the future.

**SEPSIS, AKI AND MORTALITY. SEARCHING FOR NEW MARKERS: OUR EXPERIENCE WITH ENDOGENOUS OUABAIN**

Davide Raimondo, Chiara Livia Lanzani, Luca D’urbano, Lorenzo Cocchini, Marta De Filippo, Giuseppe Vezzoli, Lorena Citterio, Laura Zagato, Paolo Manunta and Marco Simonini

San Raffaele Hospital, Milano, Italy

**Background and Aims:** Sepsis and septic shock are quite common events in the hospital setting. The classification of these events has changed a lot over the years, to ensure better sensitivity in recognizing a situation that, if not managed properly and quickly, leads to the death of the patient. In our study we focused on the search for predictors of acute kidney injury and mortality during the evolution of this pathology, with particular attention to the role of the Endogenous Ouabain hormone.

**Method:** We enrolled 177 patients diagnosed with sepsis or septic shock, under an ordinary hospital stay. We standardized patients according to the latest classification criteria (Sepsis-III), we focused our attention specifically on SOFA score and the relationship with acute kidney injury and mortality, including its relationship with other laboratory parameters, especially lactates. In a subgroup of patients was also dosed the level of Endogenous Ouabain (EO - hormone produced by the adrenal glands but which has an important impact on renal hemodynamics), through a venous sampling in 3 different times (at the beginning of the septic state, 24 and 48 hours later). Subsequently the variation of EO and the correlation with laboratory parameters was investigated in this period, to assess its impact on the development of kidney damage and mortality.

**Results:** The 70.1% of septic patients in our study develop AKI and, of this percentage, 75% in a severe form (stage 2-3 KDIGO). Both the presence and severity of AKI are unable to predict mortality in our sample (p-value 0.13). The presence of an impaired hemodynamics status (expressed as AD MAP < 70 mmHg) has a strong impact in the severe stages of AKI but not in the mild form (p-value 0.006; ExpB 1.81 vs p-value 0.105; ExpB 1.46). The other elements related to the development of AKI were found to be the high levels of white blood cells, respiratory distress and the SOFA value at the presentation, while we found no correlation with CRP and lactate levels. Lactate levels well correlate with SOFA (p-value <0.0001 and Pearson’s index 0.407) and mortality, particularly when the initial values are > 2mg/dL (p < 0.0001; ExpB 5.31, IC95% [2.07-13.57]). In the subgroup of patients in which EO was dosed, there was a strong correlation of the basal levels of this hormone with mortality even after correction for lactate levels and SOFA (p-value 0.009) but not with the development of AKI. However, patients in AKI stage-3 show persistently higher levels of EO both at 24 and 48 h (p = 0.015).

**Conclusion:** The presence of high levels of lactates at the onset is the most important predictor of mortality, followed by EO levels at presentation and the SOFA value. Elevation of Endogenous Ouabain levels is indicative of an acute state of stress but is not a parameter influenced by the SOFA score, nor by the general condition of patient. It seems non directly related with the development of AKI, tissue hypoperfusion or activation of the inflammatory response but is associated with an inability to rapidly recover renal function. The EO could be very useful in predicting mortality in patients with sepsis and septic shock as it seems to be an earlier, more specific, and sensitive than the other laboratory parameters used so far.

**HYPERURICEMIA AND HIGH URINARY URIC ACID LEVELS ARE THE NEW EARLY PREDICTORS OF CONTRAST-ASSOCIATED ACUTE KIDNEY INJURY**

vilma Cadril,1 Loriana Toska1, Ariana Strakosha1, Elvana Rista2, Nevi Pasko1, Matilda Imeraj 1, Myftar Barbullushi1 and Alban Dibra3

1University Hospital Center “Mother Teresa”, Tirana, Albania, Department of Nephrology, Tirana, Albania, 2Hygeia Hospital, Tirana, Albania, Department of Nephrology, Tirana, Albania and 3University Hospital Center “Mother Teresa”, Tirana, Albania, Department of Cardiology, Tirana, Albania

**Background and Aims:** Contrast associated acute kidney injury (CA-AKI) is recently evidenced with lower frequency although yet worldwide its incidence
ranges from 0-24%. Recent studies and meta-analysis have reported that hyperuricemia seem to be a useful biomarker in the early prediction of CIN incidence. The role of urine pH and spot uric acid to creatinine ratio (UACR) provide controversial evidence on the occurrence of CA-AKI. This research aims to gather evidence on the effect of uricemia, urine pH and UACR on the development of CA-AKI in acute conditions like primary percutaneous coronary interventions (PCI).

Method: A sample of 100 patients who underwent emergency coronary angiography in Cardiology Intensive Care Unit/UHCN-Tirana/Albania from October 2021- March 2022 were enrolled. Among these patients CA-AKI incidence was monitored, while CA-AKI was defined as an increased creatinine levels of more 25% of the baseline in a time window of 48-72h after the contrast. The analyses of the results were performed using ANOVA test for differences in parameters among CA-AKI/Non – CA-AKI patients. In order to understand the effect of each factor on the probability of experiencing CA-AKI a binary logistic regression model was constructed. Statistical analyses were performed using R-software.

Results: The general incidence of CA-AKI is 40%, while being different for men and women, with men incidence being 60%. The mean age for the patients observed was age 64.7 years old. The ANOVA analyses showed that incidence of patients experiencing CA-AKI is significantly different for chronic kidney disease patients (p = 0.001, OR = 32.67 (95% CI 9.65-110.55), patients with diabetes (P = 0.0033, OR = 4.64 (95%CI 1.69-12.68) and hypertension (p = 0.055, OR = 7.80 (95%CI 0.96-63.56). The binary logistic regression showed that probability to experience CIN is significantly impacted by UACR post contrast model 1:3.123 (2,385) with marginal effect 22.72, BMI index model 1: (-0.850) 0.25 with marginal effect 1.28, Uricemia model 1: (1,128) 0.52 with marginal effect 1.68 and Natremia level before contrast model 1: (-1.831) 0.0011 with marginal effect 7.81. Statistical significance for these results is 99% (as manifested by p-value).

Conclusion: CA-AKI post PCI is still the Achilles Heel of interventional cardiology. The results confirm that the increase of uricemia and BMI doubles the risk for CA-AKI. Uricemia is confirmed as an important prognostic factor for development of CA-AKI. High urinary uric acid levels post contrast define UACR independent early risk factor for CA-AKI.

INCREASING THE USE OF REGIONAL CITRATE ANTICOAGULATION FOR CKRT IN A LARGE TERTIARY CENTER: A QUALITY IMPROVEMENT PROJECT

Jie Ming Nigel Fong1, Maria Erika Ramirez1, Kundan Saripalli Reddy2, Yik Hang Aaron Kong1, Ting Ting Serence Koh4, Weiyan Chua4, Ratna Bte Abdul Rahman5, Wan Qi Ho6, Manish Kaushik7 and Hui Lin Lina Choong1

1Singapore General Hospital, Renal Medicine, Singapore, 2Singapore General Hospital, Respiratory & Critical Care Medicine, Singapore, 3Singapore General Hospital, Anesthesia, Singapore, 4Singapore General Hospital, Division of Nursing, Singapore and 5Singapore General Hospital, Division of Medicine, Singapore

Background and Aims: To maintain Continuous Kidney Replacement Therapy (CKRT) circuit patency, KDIGO recommends Regional Citrate Anticoagulation (RCA) as the first-line anticoagulation strategy. In a randomized controlled trial, RCA was associated with increased filter life, reduced circuit downtime, and reduced bleeding, as compared with heparin anticoagulation [1]. RCA-CKRT uptake in our institution, a 1800-bed tertiary center with seven intensive care units (ICU), was low at only 10% of all CKRT sessions. We conducted a Quality Improvement project to increase the uptake of RCA-CKRT in medical and surgical intensive care units in our institution.

Method: Following established Quality Improvement methodology, we delineated a process map and performed a root-cause analysis. Multiple plan-do-study-act (PDSA) cycles were conducted. A bespoke CKRT audit dashboard was created to automatically compile electronic CKRT prescription records and circuit monitoring data. The primary outcome measure, the percentage
Results: Problem analysis (Figure 1) identified that the top root causes contributing to low RCA-CKRT uptake rate were (1) renal physicians defaulting to ‘old habits’ of non-RCA CKRT, (2) nursing staff having inadequate experience and concerns of increased workload, (3) ICU team being uncomfortable with RCA-CKRT, especially fear of citrate toxicity. Multiple PDSA cycles were conducted. In PDSA cycle 1, inclusion and exclusion criteria for default RCA use were standardized. A poster was created to set out these criteria, along with a visual guide explaining how RCA works, and how to identify citrate toxicity. The poster was designed to be eye-catching and easy to understand for non-renal physicians, and was placed prominently in ICU and renal work areas. PDSA cycles 2-4 were educational efforts, including a peer review learning for the renal department, incorporating RCA into ICU resident didactic teaching, and an RCA refresher course for ICU nurses. Through these four PDSA cycles, all three top root causes identified were addressed in turn. Continuous feedback was sought from all stakeholders and acted on in a timely manner. For example, it was identified that some prescribers and nursing staff had the misconception that switching from non-RCA to RCA-CKRT would require changing the entire filter circuit, leading to reluctance to switch to RCA once a CKRT circuit was running. A clarification was promulgated and added to the poster. Over a 12-month period, the percentage of all CKRT sessions utilizing RCA increased from a baseline of 10.5% ± 7.7% (mean ± SD; median 9.8%) to 22.5% ± 14.6% (median 21.5%; p = 0.022) (Figure 2). This included a 3-month period after PDSA cycle 1 during which supplies of RCA-CKRT fluid were disrupted due to COVID-19 supply chain issues. Excluding the months of supply disruption, the uptake of RCA-CKRT would have been 25.3% ± 15.8% (median 25.0%).

Conclusion: A quality improvement project successfully increased the uptake of RCA-CKRT from 10.5% to 22.5% in a complex tertiary care setting. Understanding key barriers at each stage of a complex process, availability of real-time audit data, and attention to stakeholder feedback were key factors that enabled successful change. Unexpected events (in this case a supply chain disruption) may threaten a loss of momentum for change, but can be overcome with continual stakeholder engagement and additive PDSA cycles.

REFERENCE

Background and Aims: In patients undergoing cardiac surgery with cardiopulmonary bypass (CPB), pre-existing chronic kidney disease (CKD) confers a substantial risk for poor outcomes, including the development of cardiac surgery-associated acute kidney injury (CSA-AKI). CSA-AKI occurs in $\geq 50\%$ of patients with CKD undergoing cardiac surgery with CPB vs $\sim 20\%$ of patients without CKD.$^{1,2}$ The risk of subsequent Major Adverse Kidney Events (MAKE; a composite of sustained kidney dysfunction, initiation of dialysis, and death) is also elevated in patients with CKD. Causes of CSA-AKI are multifactorial and complex, and may include inflammation, oxidative stress, renal congestion, and ischaemic injury (such as ischaemic-reperfusion injury [IRI]). IRI is a common cause of AKI and typically results from early hypoperfusion while on bypass, followed by kidney injury upon reperfusion. There are currently no approved therapies that reduce the risk of AKI and associated poor outcomes after cardiac surgery with CPB.$^{3}$ Preclinical and clinical studies suggest that damage and inflammation caused by IRI and CPB is amplified by complement activation$^{3}$; early treatment with C5 inhibitors, especially before onset of ischaemia, may lower the risk of damage.

Method: ARTEMIS is a Phase 3, randomised, double-blind, placebo-controlled, multicentre study of ravulizumab in adults with CKD and stable cardiac disease undergoing non-emergent sternotomy with CPB, to reduce the risk of post-operative AKI and subsequent MAKE 90 days post-surgery.

Key inclusion and exclusion criteria can be found in Figure 1 and a study schematic in Figure 2. Briefly, the study consists of an up to 28-day screening period, randomisation and dosing 1–7 days prior to surgery with CPB (Day 1), a 90-day primary evaluation period post-CPB, and a survival follow-up at day 365 post-CPB. Approximately 736 participants will be randomised 1:1 to receive a single weight-based dose of ravulizumab or placebo; randomisation will be based on baseline CKD stage (3A, 3B, 4) and surgery type (mitral valve replacement or combined procedures vs other single procedures). The primary objective of this study is to assess the efficacy of ravulizumab in reducing the risk of MAKE$^{90}$, defined as meeting $\geq 1$ of the following by day 90 post-CPB: $\geq 25\%$ sustained decrease from baseline in estimated glomerular filtration rate (calculated using the Chronic Kidney Disease Epidemiology Collaboration equation, based on serum Cystatin C); initiation of renal replacement therapy; death from any cause. The safety of ravulizumab in participants with CKD undergoing non-emergent CPB will also be evaluated. Other secondary objectives include assessment of ravulizumab efficacy for reducing AKI (based on serum creatinine) and MAKE risk at earlier timepoints following CPB, alongside any effects it may have on healthcare resource utilisation and health-related quality of life – as well as treatment immunogenicity – in participants with CKD undergoing non-emergent CPB.

Results: The final analysis will be conducted when all participants have completed the primary evaluation period.

Conclusion: The aim of this study is to assess whether terminal complement inhibition with ravulizumab is safe and effective in reducing kidney injury and improving outcomes in patients with CKD undergoing cardiac surgery with CPB.

Abstracts
Background and Aims: Acute kidney injury (AKI) is a common clinical condition among patients who undergo cardiac surgery, significantly affecting morbidity and mortality[1]. To date, preoperative biomarkers and solid predictive models for AKI are not yet currently available in clinical practice. Recent studies reported endogenous ouabain (EO), a stress hormone secreted by the adrenal glands, as associated to worse kidney outcomes after cardiac surgery[2]. The aim was to validate the use of EO as biomarker of individual susceptibility for AKI after cardiac surgery and to create a new powerful score for postoperative AKI risk.

Method: 1174 patients undergoing elective cardiac surgery were enrolled in the study. Preoperative biological samples were collected and analysed. The primary outcome was AKI development, according to KDIGO 2012 guidelines. Results: 21.6% of patients developed AKI (9% developed severe AKI, stage ≥2). AKI confirmed strong correlation to postoperative death: all patients dead within 90 days for postsurgical complication developed AKI and each AKI stage was associated to a 10 times higher mortality risk (p < 0.001). Different preoperative clinical variables were analyzed, identifying five independent risk factors significantly correlated to AKI and severe AKI: age, FE, NYHA class, preoperative EO levels had greater incidence of AKI (p < 0.001), and reoperation and complex surgical intervention (p < 0.001 for all of them). Preoperative EO levels turned out significantly associated to the incidence of AKI (p < 0.001) and clinical complications. Specifically, patients with higher EO levels had greater incidence of AKI (p < 0.001) and worse cardiac and kidney basal function (p = 0.005 and p = 0.003, respectively). Finally, a simple score was developed based on the base of those preoperative clinical variables significantly associated to AKI (AUC for severe AKI = 0.79, p < 0.001). Adding preoperative EO to the model significantly improved the predictive capability (AUC for severe AKI = 0.82, p < 0.001; Δ-AUC +0.0229, p = 0.026).

Conclusion: We confirmed in a large population the role of preoperative plasma level of EO as an important early predictor for post-surgical AKI and we built a powerful clinical model for postoperative AKI risk, exclusively using few simple preoperative clinical factors and a single biohumoral marker.

A NEW ADJUNCTIVE THERAPY WITH AVACOPAN FOR ANCA-ASSOCIATED VASCULITIS
Ryuichi Yoshii¹, Kengo Kajiwara¹, Koki Matsushita¹,
Tomohumi Nakamura¹, Masao Tomita¹ and Masashi Mukoyama²
¹National Hospital Organization Kumamoto Medical Center, Japan and
²Kumamoto University Hospital, Japan

Background and Aims: Glucocorticoids have been the standard treatment for anti-neutrophil cytoplasm autoantibody-associated vasculitis (AAV). Avacopan, a complement CsA receptor inhibitor, has been approved for the treatment of AAV in Japan, the USA, Germany, and Austria. The use of avacopan is supported by evidence from trials demonstrating disease remission with limited use of glucocorticoids [1–3]. Avacopan is a new, promising adjunctive agent for standard induction therapy for AAV and may potentially reduce steroid use.

Method: We assessed treatment responses of patients with AAV who did not require dialysis between 2018 and 2023. Group 1 consisted of six adult patients who were treated with avacopan (30 mg, twice daily) plus reduced-dose prednisone, and Group 2 consisted of 14 patients who received high-dose prednisone. We compared the mean dose of prednisone, Birmingham Vasculitis Activity Score (BVAS), creatinine, urine protein/creatinine ratio (UPCR), and C-reactive protein (CRP) at weeks 0 and 12 between the two groups.

Results: The mean total prednisone dose of oral glucocorticoids at both weeks 0 and 12 was much lower in Group 1 than in Group 2 (p < 0.05). Mean BVAS, creatinine, UPCR, and CRP in Group 1 was comparable to Group 2. Steroid-related toxicity occurred in three of six (50%) patients in Group 1, and 5 of 14 (36%) patients in Group 2. Liver damage related to avacopan occurred in two of six (33%) patients in Group 1.

Conclusion: Herein, we describe practice observations on the use of avacopan in patients with AAV. While further studies are needed to confirm the efficacy of avacopan because of the number of cases treated with avacopan is still lacking, our findings suggest that avacopan was beneficial in AAV patients because of the absence of steroid dependence.

REFERENCES
patients (17.6%) developed a thrombotic complication, whereof 13 (7.4%) were acute coronary syndrome (ACS) or ischemic stroke (IS). The Odds Ratio (OR; 95% CI) to develop any thrombosis for patients with T-TAS01 measurements below (PL-AUC) or above (AR-OT) median were 0.14 (0.05-0.40) and 0.28 (0.12-0.67), respectively. ROC analyses to predict thrombosis with T-TAS01 showed AUCs of 0.78 for all thrombosis and 0.62 for ACS/IS (PL-AUC and AR-OT data combined).

Conclusion: T-TAS01 is a promising tool to aid in the prediction of bleeding and thrombosis in HD patients.

#6306 SUSTAINED LOW-EFFICIENCY DIALYSIS VERSUS CONTINUOUS VENO-VENOUS HEMODIALFILTRATION OUTCOME IN CRITICALLY ILL PATIENTS

Abdelrahman Marzouk Abd Elaziz1, Ahmed Soliman2, Bassham Ahmed1, Abdelrahman Hossam3, Emam Elshehri1 and Yasser Abdelhamid1
1Faculty of Medicine-Cairo University, Nephrology Division-Internal Medicine Department, Cairo, Egypt and 2Faculty of Medicine-Cairo University, Critical Care Department, Cairo, Egypt

Background and Aims: Acute kidney injury due to sepsis is the most common cause of AKI in critical care settings. Different modalities of renal replacement therapies (RRT) have been used to manage this condition including Continuous Renal Replacement Therapy (CRRT) and sustained low efficiency dialysis (SLED). The aim of this work was to compare the outcome of SLED and CRRT in the form of continuous veno-venous hemodiafiltration (CVVHF) as methods of dialysis in sepsis induced AKI.

Method: We retrospectively analysed data from 120 patients; 20 patients received CVVHDF to manage AKI in the context of sepsis, 47 patients received SLED to manage AKI in the context of sepsis and the third group included 53 patients who have been treated with SLED to manage AKI not due to sepsis. Age was found to be significantly higher in sepsis induced AKI patients treated with SLED than patients treated with CVVHDF (65.5±10.1 vs 59.5±9.3; p = 0.03). Sex distribution or incidences of hypertension, diabetes mellitus, malignancy or liver disease were not statistically different between groups.

Results: Unadjusted 30 day mortality was 44.7% (21pt) in the SLED group vs 50% (10pt) in the CVVHDF group; p = 0.07. Adjusted mortality was not statistically significant between SLED and CVVHDF (OR 0.97, CI = 0.95-1.06). Hypotension occurred more frequently in patients treated with SLED (24 pt = 51.1% vs 5 pt = 25%; p < 0.001).Clotting occurred more frequently in the CVVHDF group as compared to SLED group (7 pt = 35% vs 4pt = 8.5% p < 0.001).

Conclusion: Sustained low efficiency dialysis (SLED) and CVVHDF had comparable 30 day mortality as modalities of RRT in critically ill patients with sepsis induced AKI. SLED still an attractive alternative to CRRT modalities due to lower cost and lower incidence of complications. Further larger studies are recommended.

#3829 ARTERIAL STIFFNESS AND METABOLIC SYNDROME INDICES IN RENAL TRANSPLANTATION PATIENTS

Orkhan Guliyev1, Ayten Mamedzade2, Shalah Imsayilova2 and Jabrayil Jabrayilov2
1Baku Health Center, nephrology, Azerbaijan and 2Azerbaijan

Background and Aims: Although renal transplantation improves survival, cardiovascular morbidity and mortality still remain as a significant problem compared with nonrenal populations. In end stage renal disease metabolic cardiovascular risk factors such as hypertension, hyperuricemia, obesity and diabetes mellitus have been confirmed to be positively correlated with arterial stiffness. Arterial stiffness is an important characteristic of the arterial wall and can be assessed noninvasively by the measurement of carotid-femoral pulse wave velocity (PWV). The aim of this study is to evaluate the risk factors for arterial stiffness in kidney transplant recipients.

Method: One hundred and forty nine kidney transplant recipients from our renal transplant outpatient clinic were enrolled into the study. All patients were evaluated for their standard clinical (age, gender, duration of hemodialysis, post-transplant time), biochemical parameters. Anthropometric and body composition analyses were performed for all patients. Body composition were analyzed by using the Body Composition Analyzer (Tanita BC-420MA). PWV was determined from pressure tracing over carotid and femoral arteries using the SphygmoCor system.

Results: Patients were divided into two groups according to PWV levels. The frequency of patients with PWV ≥ 7 m/s was higher in patients with new onset diabetes (55.9%), hyperuricemia (uric acid level type “Periodical” type= “Periodical” type= 0.12-0.67), respectively. ROC analyses to predict thrombosis with T-TAS01 showed AUCs of 0.78 for all thrombosis and 0.62 for ACS/IS (PL-AUC and AR-OT data combined).

Conclusion: In post transplantation period, metabolic syndrome indices as high blood pressure, hyperuricemia, hyperglycemia and increased waist and hip circumferences are closely related with arterial stiffness. For cardiovascular risk reduction after renal transplantation; blood pressure, serum glucose and uric acid levels should be under strict control.

#3153 HEMOPERFUSION WITH CYTOSORB AND RENAL REPLACEMENT THERAPY IN PATIENTS WITH ACUTE KIDNEY INJURY IN THE INTENSIVE CARE UNIT

Barbara Kobal1, Tea Korosce1, Eva Jakopin2, Franc Svec3, Sebastjan Bevc1,2, Radovan Holo1,2 and Robert Ekar1,2
1University of Maribor, Faculty of Medicine, Maribor, Slovenia, 2University Medical Centre Maribor, Clinic for Internal Medicine, Dept. of Nephrology, Maribor, Slovenia, 3University Medical Centre Maribor, Clinic for Internal Medicine, Dept. of Internal Intensive Medicine, Maribor, Slovenia and 4University Medical Centre Maribor, Clinic for Internal Medicine, Dept. of Dialysis, Maribor, Slovenia

Background and Aims: Severe acute kidney injury (AKI) requiring renal replacement therapy (RRT) is a serious clinical disorder in the intensive care unit (ICU), occurring in a substantial proportion of critically ill patients. The aim of our single centre retrospective observational study was to analyse the outcomes of patients admitted to a non-surgical ICU and treated with RRT and with/without continuous hemoperfusion with Cytosorb.

Method: One hundred critically ill patients (mean age, 64.3 years; 69 men) admitted to the ICU and requiring RRT for AKI were analysed. Patient demographics, comorbid diseases, type of RRT, and survival were obtained from the medical record. APACHE II and Sofa Scores on admission were calculated. 30-day mortality was assessed using Kaplan-Meyer or Cox proportional hazards models.

Results: Reasons for ICU admission were acute respiratory failure (39%), cardiopulmonary resuscitation (14%), shock (13%), acute coronary syndrome (9%), sepsis (3%), acute pancreatitis (3%), and other (19%). Prior comorbidities were hypertension (70%), diabetes (43%), heart failure (32%), chronic kidney disease (CKD) (30%), coronary artery disease (CAD) (27%), chronic obstructive pulmonary disease (COPD) (15%), malignancies (12%). Eighty-six patients were treated with continuous RRT (CRRT) and 14 with intermittent hemodialysis (HD). Twenty-four (24%) of patients treated with CRRT were also treated with hemoperfusion with Cytosorb. Using an independent-samples T test, we compared the two groups of patients with respect to the use of Cytosorb (Table 1). 30-day mortality was 82% in all patients and 87.5% in patients treated with CRRT and Cytosorb. Among concomitant diseases, only patients with previous heart failure had worse survival (p = 0.032), previous CKD, CAD, COPD, malignancy had no statistically significant impact. We found no statistically significant differences in 30-day mortality between patients treated with CRRT+Cytosorb and patients treated with CRRT or HD alone. Multivariate Cox proportional hazard regression showed that of all the variables in the statistical model (age, sex, body mass index, previous diseases, C-reactive protein, lactate, procalcitonin, serum creatinine, mean arterial pressure, APACHE II, ultrafiltration between CRRT), only lactate levels on admission (p = 0.002; 95%CI 1.08-1.38) were significant predictor of survival.

Conclusion: The use of hemoperfusion with Cytosorb in ICU patients with AKI did not reduce 30-day mortality. Patients with prior heart failure had a worse outcome. Serum lactate levels at ICU admission were an independently highly prognostic factor for death within 30 days of admission.

RELATIONSHIP BETWEEN URINARY DCR2/CR LEVEL AND POOR PROGNOSIS OF DIABETIC NEPHROPATHY

Weidong Wang, Jia Chen, Yani He and Kehong Chen

Daping Hospital, Army Medical University, Department of Nephrology, Chongqing, P.R. China

Background and Aims: Diabetic kidney disease (DKD) has a high prevalence rate and many complications, and it has become the main reason for the progression of chronic kidney disease to end-stage renal disease (ESRD). At present, some clinical biomarkers, such as urinary albumin/creatinine ratio (ACR), serum creatinine and cystatin C, are of positive significance in evaluating the course of DKD, but these indicators are greatly affected by the state of the body itself, which can no longer meet the clinical needs. Decoy receptor 2 (DcR2) is the transmembrane receptor of tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) and is a biomarker of cell senescence and apoptosis resistance. Our previous study found that the level of urinary DcR2/CR is closely related to renal function damage and renal interstitial injury. Considering that there is still a lack of research on predicting the poor prognosis of DKD with related biomarkers, this study detected the level of DcR2/CR in the urine of patients with DKD for the first time to analyze the relationship between the poor prognosis of DKD and to determine whether urinary DcR2/CR can be used as an index to predict the poor prognosis of DKD.

Method: A total of 181 inpatients with DKD were collected from the Department of Nephrology of Daping Hospital from 2018 to 2022, of which 121 urine samples were collected. The clinical data of the patients were collected and divided into three quantiles according to the level of urinary DcR2/CR. Group 1: DcR2/CR < 321 ng/mmol, group 2: 321 ≤ DcR2/CR ≤ 505 ng/mmol, group 3: DcR2/CR > 505 ng/mmol. The adverse prognosis was based on the occurrence of end point events. Multivariate Cox regression analysis was used to evaluate the relationship between urinary DcR2/CR level and poor prognosis of DKD. ROC curve was used to analyze the value of biomarkers in predicting the poor prognosis of DKD.

Results: With the increase of urinary DcR2/CR level, the levels of urinary microalbumin, ACR, NAG, cystatin C and serum creatinine increased, while urinary creatinine and GFR decreased gradually. Correlation analysis showed that the level of DcR2/CR was positively correlated with ACR, cystatin C and NAG, and negatively correlated with eGFR, while DcR2/CR was positively correlated with IFTA score, renal artery hyaline change score and renal arteriosclerosis score. Cox regression analysis showed that there was a significant correlation between the level of DcR2/CR and the occurrence of poor prognosis (corrected by the model), and the risk of poor prognosis in the DcR2/CR group 3 was 9.903 times higher than that in the DcR2/CR1 group. Kaplan-Meier survival curve showed that the higher the level of DcR2/CR, the worse the prognosis. ROC curve analysis showed that the area under urinary DcR2 curve was the largest (AUC = 0.811), which was higher than ACR, CYC and SCR, and the best intercept value was 389.0 ng/mmol.

Conclusion: Urinary DcR2/CR is superior to ACR, Scr, CyC and other clinical indexes in predicting the poor prognosis of DKD. It is an effective biomarker for predicting poor prognosis of DKD.

CAUSES OF PEDIATRIC END STAGE KIDNEY DISEASE IN SUDAN

Rasha Hussein1, Xiaoling (Janice) Ye2, Rashid Elldiri4, Elitigani Ali1, Yassir Bakhiet1, Mohamed Karar1, Mohamed YoussiF1, Ghassan Mustafa1, Nahla Allam1, Samira Yahia1, Amna Ahmed1, Mohamed Abdelraheem1 and Peter Kotanko2

1Soba University Hospital, Department of Pediatric Nephrology, Khartoum, Sudan and 2Renal Research Institute, New York, United States of America

Background and Aims: Sudan is a large Sub-Saharan country with a population of about 48 million people, 41% of them under the age of 15 years and a median age of 18.9 years. To data, no data have been reported on the etiology of end stage kidney disease (ESKD) in children and young adults of less than 18 years of age.

Method: We conducted a chart review of all ESKD patients below the age of 18 years treated in a tertiary referral center, the Soba University Hospital (SUH) in Khartoum, the capital of Sudan. The research was approved by the SUH ethical committee. We report descriptive statics, including age, sex, ESKD causes, and kidney biopsy frequency.

Results: We included 885 patients in this analysis, their mean age (SD) was 12 (3.0) years and 57.7% were males. Glomerulonephritis, mostly post-streptococcal glomerulonephritis, was the leading cause of ESKD (36.8%), followed by unknown etiologies (25.3%) and congenital anomalies of kidney and urinary tract (CAKUT; 14.9%). In most patients with glomerulonephritis the diagnosis was based on kidney histology (96.6%). ESKD was attributed to HUS in about 7% of patients. As expected, SLE was more prevalent in females (3:1 ratio) and hereditary nephritis in males (3:1).

Conclusion: Glomerulonephritis and CAKUT account for over 50% of pediatric ESKD patients in this study from a tertiary referral center in Sudan.

transplantation. In the first case we observed a functional recovery from the first dose with no notable adverse effects up today, as in the post-transplant patient, maintaining a good control of TMA despite more spaced dosing (8 weeks). The inclusion of this drug in the therapeutic arsenal opens a new safe treatment route in pediatric patients with HUSAs.

**RAVULIZUMAB "DE NOVO" IN PEDIATRIC PATIENTS WITH ATYPICAL HEMOLITIC UREMIC SYNDROME: FIRST WORLDWIDE CASES**

Pedro Arango Sancho 1, Osmar David Gonzalez 2, Ana Cristina Aguilar Rodriguez 1, Marta Jiménez Moreno 1, Elena Codina Sampera 1, Bernat Gómez Herrera 2, Raquel Jiménez García 1, Yolanda Calzada Baños 1, Verónica Coll Brito 3 and Álvaro Madrid Aris 4

1 Hospital Sant Joan de Déu, Pediatric Nephrolgist, Barcelona (Esplugues de Llobregat), Spain, 2 Pontificia Universidad Católica de Chile, Pediatric Nephrology, Santiago de Chile (Región Metropolitana), Chile and 3 Fundación Puigvert, Nephrology, Barcelona, Spain

**Background and Aims:** Ravalizumab is a long-acting C5 inhibitor that has recently demonstrated its effectiveness in adult and pediatric patients for the control of hemolytic uremic syndrome compared to eculizumab, allowing average annual infusion times of up to 70% less. There is still little evidence in the literature of naïve treatment with this drug in pediatrics.

**Method:** We present the first two pediatric cases worldwide with the use of de novo Ravalizumab: the first one in the onset of the disease and the second one, post-kidney transplant.

**Results:** 13-year-old girl referred from another country with 1 week history of acute gastroenteritis with bloody stools, vomitting and compromise of consciousness. Deterioration of general condition, with laboratory tests compatible with thrombotic microangiopathy (TMA), evolves to anuria and convulsive episode requiring invasive mechanical ventilation, corticosteroid boluses, 6 plasmapheresis sessions and 4 intermittent hemodialysis. One Eculizumab dose (600 mg) was administered in the center of origin and STEC was isolated. At admission presented compromised renal function (AKI III), hemolytic anemia, thrombocytopenia, normal ADAMTS-13, negative direct Coombs and decreased complement. Brain MRI study shows images compatible with multiple foci of necrosis. Due to the persistent requirement of renal replacement therapy and persistent TMA, Ravalizumab was started with a loading dose (2400 mg) and a second dose after 2 weeks. The need for renal replacement therapy ceased with improvement of hemolysis and renal function. Genetic study showed mutation of uncertain significance in heterozygosis in exon 6 (c.881_883 p.Ala292del) with risk polymorphism for HUSAs (deletion CFHR3-CFHR1).

**Case 2:** 7-year-old girl (stage 5 CKD) in chronic hemodialysis 3 times/week secondary to aHUS (CD46 mutation) was admitted for kidney transplant from a living donor (father), performing hemodialysis session before surgical intervention. Low-intermediate immunological risk (PRA 0%, 9 HLA matches) and high CMV infectious risk (valganciclovir prophylaxis). Induction treatment: Basiliximab, tacrolimus, mycophenolate and steroids. First dose of Ravalizumab was infused the day before transplantation (900mg), well tolerated. 36 hours after presented acute pulmonary edema as well as a drop in hemoglobin (4g/dL). With normal laboratory hemolysis parameters, urgent abdominal-pelvic CT was performed due to suspicion of bleeding, confirming an active bleeding. Surgical reintervention was decided due to uterine bleeding and the tunnel was redone with good results. The patient has had a favorable evolution of renal function, with a normal value of creatinine at discharge (0.43 mg/dL). Protein/Creatinine urine ratio (iPr/Cr) increases to a maximum of 8 mg/mg. Negative DSA levels but the option of renal biopsy was assessed and ruled out due to a decrease in proteinuria (iPr/Cr 0.51 mg/mg). She received second dose of ravalizumab after 2 weeks, remain stable with no data on recurrence of the underlying disease today.

**Conclusion:** In the two patients, the initial treatment with Ravalizumab was satisfactory, both in the acute phase of the disease and in the immediate post-

**ACUTE KIDNEY INJURY IN PATIENTS WITH VENTRICULAR SEPTAL RUPTURE: A SINGLE CENTER STUDY**

Rajeevalochana Parthasarathy, Anu Jacob, Deepak Selvanathan and Veena S

The Madras Medical Mission Hospital, Chennai, India

**Background and Aims:** Ventricular septal rupture (VSR) is an infrequent but dreaded complication of acute myocardial infarction (AMI). Acute kidney injury (AKI) is one of the major determinants of morbidity and mortality in these patients. Renal replacement therapy (RRT) is, in this set of patients of high-risk nature and can be prolonged. Focused data on the management of AKI in patients with VSR from developing countries is scarce. We present a large cohort of patients presenting with VSR from a tertiary care Centre in South India, evaluating the incidence of AKI, RRT and short-term outcomes in this cohort.

**Method:** Observational study of all adult patients diagnosed with VSR following AMI over 5 years in a single centre in Chennai, India. Demographic characteristics, co-morbidities, clinical and laboratory; Serial renal function tests and urine output was noted. eGFR was calculated using the CKD-EPI formula. AKI definition and staging- KDIGO clinical Practice Guidelines. Data analysis was done using the IBM SPSS version 24. P-value less than 0.05 is used to indicate statistical significance.

**Results:** During the study period, 3024 patients presented to our hospital with acute coronary syndrome (ACS) and seventy patients presented with VSR (2.3%). Of these, forty-seven (67.1%) developed AKI. A nephrology consult was obtained for thirty-three (70%) patients. Older age, higher total count and lower systolic blood pressure were significantly associated with the occurrence of AKI. The mortality in the AKI group was significantly higher (63.8%). VSR closure was done in 12.7% and 21.7% of the AKI and non-AKI groups respectively. Surgical VSR repair was done in 61.7% and 60.8% of the patients with and without AKI respectively. Most of the patients (26, 53.3%) presented with KDIGO stage 3 AKI and all were oliguric. 10 and 11 patients were staged into KDIGO stages 1 and 2 respectively. 26 patients with Stage 3 AKI, only 14 (29.7%) of them received nephrology consult. RRT was initiated in fifteen patients (31.9%). The indications for RRT were oliguria, pulmonary oedema, metabolic acidosis, and worsening electrolyte disturbance. Acute peritoneal dialysis was initiated in 11 patients (73.3%) using a 43cm swan neck double cuffed tunnelled Tenckhoff peritoneal dialysis catheter placed at the bedside. Perventricular peritoneal dialysis catheter insertion by a nephrologist was done in and the rest was inserted by open laparotomy technique by a trained general surgeon. All 11 were initiated on urgent low volume supine exchanges. Of these ten patients had manual exchanges done by a trained peritoneal dialysis nurse and one patient was put on automated peritoneal dialysis. The average volume per dwell was 500 ml±250 ml which was gradually increased if there was no leak. The total average peritoneal dialysis volume per day was 101±42 L. The strength of bags (1.36%, 2.25%, 3.86%) dextrose was determined based on volume status and patients’ hemodynamics. No patient had a leak or peritoneal dialysis-related peritonitis. All patients’ peritoneal dialysis catheter was immobilized with a tight abdominal dressing. One patient continued continuous ambulatory peritoneal dialysis at home as there was no recovery of renal function and was lost to follow up. Sustained low-efficiency
dialysis was performed on four patients. Duration of Sustained low-efficiency dialysis ranged from 6-8 hours with average blood flows of 150 ml/min and average fluid removal between 1.5-3L. Unfractionated heparin was used in three patients, and one was heparin free saline dialysis. Discharge eGFR in the AKI group was significantly lower as compared to the non-AKI group. (38 vs 104ml/min/1.73m², p<0.001). Follow up was done on 14 at 3 months. The mean eGFR was 57.8ml/min/1.73 m² when compared to 81.8 ml/min/1.73 m².

**Conclusion:** The incidence of AKI is high and is associated with a high rate of mortality in patients with VSK. Peritoneal dialysis is a safe and effective option for those patients requiring RRT. Follow up of AKI patients at three months did not show a significant decline in renal function

#6070

**PREDICTIVE MODEL OF OBSTETRIC ACUTE RENAL FAILURE IN THE INTENSIVE CARE UNIT**

Yassine Hafiani¹, Anas Erragh², Ibtiissam Nabih³, Mohammad Khalayla¹, Ihsane Moussaid², Smael Elyoussoufi² and Said Salmi²

¹CHU Ibn Rochd, Anesthésie-Réanimation, Casablanca, Morocco and ²CHU Ibn Rochd, Anesthésie-Réanimation, Casablanca, Morocco

**Background and Aims:** Obstetric acute renal failure (OARF) remains a frequent and serious complication that engages the maternal and fetal prognosis. The objective of our work is to develop a predictive model of obstetric acute renal failure in the intensive care setting.

**Method:** To meet our objective we conducted a retrospective comparative and analytical study spread over a period of 7 years, from January 2014 to September 2021 within the obstetric resuscitation department of ABDERAHIM HAROUCHI hospital of CHU Ibn Rochd of Casablanca. We have thus distinguished two groups of parturients:

- Group 1 “OARF +” : parturients with ARF (n = 863)
- Group 2 “OARF -” : parturients without ARF (n = 1856)

**Results:** During this period 2719 obstetric admissions in intensive care were collected including 863 cases of ARF that we classified according to the KDIGO classification with a percentage of stages I, II and III respectively of 45.2%, 28.5% and 25.3% of cases. The average age of our OARF+ sample was 28.6±5.4 years. 40% of the parturients in this group were primiparous and 60% were multiparous, with the majority of cases occurring between 20 and 28 weeks' gestation (32%). OARF was associated with pre-eclampsia in 57% of cases, hemorrhagic shock in 37.19% of cases and severe sepsis in 31.74% of cases. Extra renal purification was necessary in 148 parturients (17.2%) and the mortality rate in the OARF+ group was 26.18%.

In univariate analysis, the clinico-biological risk factors for the occurrence of obstetric ARF were haemostasis disorders (p < 0.001), hypertension (p < 0.001), oligo-anuria (p = 0.002), severe anaemia (p < 0.001) and thrombocytopenia (p < 0.001). As for the etiological factors, our analysis allowed us to retain pre-eclampsia (p < 0.001), hemorrhagic shock (p < 0.001), sepsis (p < 0.001),HELLP Syndrome (p = 0.002) and DIC (p = 0.002).

**Conclusion:** Pre-eclampsia, pre- and postpartum hemorrhage, and sepsis represent the main etiologies of obstetric ARF, which is a frequent obstetric complication in the ICU setting and responsible for significant maternal morbidity and mortality. The determination of the risk factors for the occurrence of such a complication allowed us to detect and prevent the patients at risk.

#3644

**CLINICAL VALUE OF SOLUBLE UROKINASE-TYPE PLASMINOGEN ACTIVATOR RECEPTOR IN DIAGNOSIS AND PROGNOSIS OF SEPSIS-ASSOCIATED ACUTE KIDNEY INJURY**

Yue Gu, Wenwen Zhang and Jing Zhou

Henan Provincial People's Hospital;Zhengzhou University People's Hospital; Henan University People's Hospital, Department of Nephrology; Henan Provincial Clinical Research Center for Kidney Disease, Henan Provincial Key Laboratory of Kidney Disease and Immunology, Zhengzhou, P.R. China

**Background and Aims:** Acute kidney injury (AKI) is a common complication of hospitalized adults with increased risk of chronic kidney disease and end-stage kidney disease. Sepsis is the most common reason of AKI in patients admitted in intensive care unit(ICU) with the incidence over 50%. Soluble urokinase-type plasminogen activator receptor (suPAR) is an important immune mediator involved in kidney injury. Numerous studies have shown that the suPAR is associated with a variety of kidney diseases.However, it remains unknown on the diagnosis and prognosis value of suPAR in sepsis-associated acute kidney injury (S-AKI). Hence, this study aimed to explore the diagnostic value for the prediction of S-AKI courses and 28-day death.

**Method:** In this prospective study, adult patients with sepsis admitted to the ICU of Henan people's Hospital from December 2020 to February 2022 were enrolled. Plasma suPAR levels at 0, 12, 24 and 48 hours after admission to ICU were measured by enzyme-linked immunosorbent assay. We assessed the development of S-AKI as the primary outcome and the occurrence of death within 28 days in patients who had S-AKI as a secondary outcome. The prediction of the suPAR level on S-AKI and death was tested using receiver operating characteristic curve (ROC) analysis, by calculating the area under the curve (AUC), and 95% confidence interval (CI).

**Results:** Of the 182 sepsis patients, 66 (36.3%) developed AKI during hospitalization, of whom 31 (46.9%) died. At 12, 24 and 48 hours after admission to ICU, the plasma suPAR level was significantly higher in patients with S-AKI than in patients without AKI (P<0.05). (Figure 1) In sepsis patients dead with 28 days after admission in ICU, the plasma suPAR level was significantly higher at 0 and 48 hours after admission in ICU compared to the survival patients (P<0.05). (Figure 1) Diagnostic performance of plasma suPAR level improved over time with the highest area under the receiver operating characteristic curve of 0.701 (95% CI, 0.623–0.779) 24 hours after study inclusion. Additionally, plasma suPAR levels at 0h have the highest area under the receiver operating characteristic curve of 0.647 (95% CI, 0.512–0.782) in predicting 28-day death. The best discrimination ability for the S-AKI was achieved for suPAR 24 hours after inclusion by applying a cutoff value of greater than or equal to 3.11 ng/mL (sensitivity 62.1, specificity 71.6). The suPAR at 0h after inclusion performed best in discriminating 28-day death by using a cutoff value of greater than or equal to 4.57 ng/mL (sensitivity 87.1, specificity 51.4).

**Conclusion:** Plasma suPAR level can be a potential biomarker for early diagnosis of S-AKI and has a certain clinical value in predicting the short-term death of S-AKI. However, further clinical studies with larger sample size is needed.
Figure 1: Comparison of suPAR levels between the S-AKI vs non-AKI groups and the survival vs death groups at 0, 12, 24 and 48 hours after admission to ICU.

#5001
AKI AND AKD AFTER RADICAL CYSTECTOMY FOR MUSCLE INVASIVE BLADDER CANCER: AN UNEXPECTED NEPHROLOGICAL AFFAIR

Francesco Trevisani¹, Mattia Longoni¹, Alessandra Cinque², Giuseppe Rosiello³, Marco Malvestiti³, Andrea Salonia¹, Alberto Briganti¹, Francesco Montorsi¹, Marco Moschini¹ and Matteo Floris³

¹IRCCS San Raffaele Scientific Institute, Department of Urology and Division of Experimental Oncology, Milan, Italy, ²Bièrek srl, Milan, Italy and ³San Michele Hospital, ARNAS G. Brotsu, Department of Medical Science and Public Health, Cagliari, Italy

Background and Aims: Radical cystectomy (RC) represents the first line surgical treatment for muscle-invasive bladder cancer (MIBC). RC is a complex surgical procedure characterized by significant morbidity and mortality. The incidence of significant complications following RC is a well-recognized issue however still paucity of data exists regarding postoperative renal function. Aim of the study was to evaluate the incidence of acute kidney injury (AKI) and Acute kidney disease (AKD) after RC, evaluating the impact of surgery (open or robotic one), comorbidities (hypertension, diabetes, CAD) and previous oncological treatments (chemotherapy, immunotherapy and radiotherapy).

Method: We collected a consecutive cohort of 839 patients who underwent RC for MIBC in a single tertiary institution between 2010 and 2022. All clinical variables and comorbidities were reported pre and after surgery. Serum creatinine with subsequently eGFR using CKD-EPI formula were collected at baseline pre-operative and in the acute setting at 24h, 48, 72h, 6 days for the AKI onset, and after 9, 12, 15, 18, 21, 24, 27, 30, 45, 60, 75, 90 days for the AKD establishment. We compared the incidence of AKI and AKD upon the two different surgical approaches for RC: the open and robotic one. Fisher’s exact test; Wilcoxon rank sum test; Pearson’s Chi-squared test were used for the statistical analyses.

Results: General characteristics of patients included in the study are summarized in Table 1. Surprisingly, a very high rate of both AKI (30%) and AKD (50%) was reported in the total cohort of patients, with an augmented incidence in the robotic surgery (p < 0.001). Moreover, stage II and III of both AKI and AKD affected a non-negligible percentage of patients, requiring advanced nephrological medical treatments and prolonged hospitalization (Table 1). The multivariate analysis showed that age, blood hypertension and BMI represent the major risk factors to develop both AKI and AKD (Table 3 and Figure 1).

Conclusion: AKI and AKD are very frequent and insidious side effects in the RC for MIBC. Therefore, a personalized nephrological counseling both in the pre and post -surgery asset is mandatory to reduce morbidity and mortality.
URINARY DCR2/Cr LEVEL PREDICTS RENAL OUTCOME IN PATIENTS WITH ACUTE KIDNEY INJURY
Xiangling Yi, Kehong Chen, Jia Luo, Jia Chen and Yani He
Daping Hospital, Army Medical University, Department of Nephrology, Chongqing, P.R. China

Background and Aims: Acute kidney injury (AKI) is a well-recognized complication of critical illness which increases the risk of morbidity and mortality. It has been reported that about 30% of AKI patients developed to chronic kidney disease (CKD), and even to end-stage renal disease (ESRD). It is urgent to explore novel biomarkers to evaluation the renal outcome of AKI. Decoy receptor 2 (Dcr2), a senescent marker, is expressed specifically in senescent tubular epithelia. And urinary Dcr2 (uDcr2) is associated with renal fibrosis in chronic kidney disease. The aim of study is to investigate the association of urine Dcr2 with renal outcome of AKI.

Method: 153 biopsy-proven AKI patients were included from Daping Hospital, Army Medical University from January 2018 to October 2022. A composite renal endpoint included creatinine more than 50% higher than the baseline or ESRD after 90 days. All patients were divided into positive endpoints (n = 75) and negative endpoints (n = 78). The clinical characteristics were collected, and the pathological injury was scored. uDcr2 levels were measured using enzyme-linked immunosorbent assay and normalized to urinary cre (uDcr2/Cr). The correlation of uDcr2/Cr levels with renal function and renal pathological scores were analyzed. The logistic regression analysis was used to investigate the association of uDcr2/Cr with renal outcome of AKI.

Results: The level of uDcr2/Cr was positively correlated with cystatin C, and negatively correlated with estimated glomerular filtration rate (eGFR). And uDcr2/Cr was positively associated with renal pathological acute scores. Univariate logistic regression results increase the risk factors for poor kidney prognosis are age, female, with hypertension or (and) CKD, eGFR, Cystine C and uDcr2/Cr. Multivariate logistic regression analysis showed that the effect of uDcr2/Cr on renal outcome was statistically significant. After a median follow-up of 16 months, 75 participants achieve endpoint and there were 16 patients with end-stage renal disease. The ROC curve was used to analyze the value of uDcr2/Cr for predicting kidney prognosis in AKI with an area under the curve of 0.72 and the cut-off value of 365ng/g Cr. The median time from at the time of AKI to endpoint in the uDcr2/Cr ≥ 365ng/g Cr group (7.6 months) was significantly shorter compared to the uDcr2/Cr < 365ng/g Cr group (36.6 months).

Conclusion: Urinary Dcr2/Cr is closely associated to kidney injury and renal prognosis of AKI, suggesting that uDcr2/Cr could sever as a novel biomarker for predicting adverse outcomes in patients with AKI.

ROLE OF STATINS IN THE CONTRAST-INDUCED ACUTE KIDNEY INJURY PREVENTION AFTER COMPUTED TOMOGRAPHY WITH CONTRAST MEDIA
Andrey Vasin, Elham Pahlevani, Valentina Biryukova, Olga Mironova and Victor Fomin
Moscow, Russia

Background and Aims: Contrast-induced acute kidney injury (CI-AKI) is a serious complication of the use of iodinated contrast media (CM). A number of researches have shown that statins have a protective role in the prevention of CI-AKI due to their pleiotropic effects. The aim of the study was to assess the influence of statins on the incidence of CI-AKI after intravenous CM administration.

Method: A randomized controlled open-label prospective study was conducted. Statin naive patients with cardiovascular diseases referred for contrast-enhanced computed tomography (CT) were included. Exclusion criteria were the use of statins and chronic kidney disease (CKD) stages 4-5. Acute kidney injury was defined as an increase in serum creatinine level by more than 44 μmol/L (0.5 mg/dL) or 25% from baseline within 48 hours after CM administration according to KDIGO guidelines. Glomerular filtration rate was calculated using the CKD-EPI formula. Overall, 181 patients were included in the study and divided into two groups. The first group (120 people) received high doses of atorvastatin (80mg or 40mg) 24 hours after and before the CM administration, while the second group (61 people), the control group, did not receive any statin therapy. Low-osmolar solutions in an amount of 100 ml were used. All patients were given intravenous hydration with saline before the study and 24 hours later. The statistical analysis was done using IBM SPSS Statistics v26.0.
Results: The patients in both groups did not significantly differ in age, BMI, coexisting conditions, and medications taken (Table 1). Both groups showed an increase in average creatinine levels after CT with intravenous contrast media. Table 2 shows an increase in average creatinine levels after CT with intravenous contrast media. In 12 individuals (6.7%), 9 of them were in the control group, and 3 were in the Statin group. The average level increased less, p = 0.06. The chances of AKI development in the group receiving high doses of statins were 6.95 times higher compared to the control group (OR = 6.95, 95% CI: 1.7-21.5). Most of the patients with preserved kidney function in the Statin group did not suffer from diabetes mellitus. There were statistically more significantly patients with preserved kidney function in the Statin group, p = 0.007, OR: 2.374 (CI 95% 1.258 - 4.479), and fewer patients with CKD 3a stage, p = 0.05, OR: 0.406 (CI 95% 0.195 – 0.844).

Conclusion: Despite the presence of patients at risk, the incidence of CI-AKI was 6.7%, possibly due to additional prevention of this complication with intravenous saline before and after administration of the CM. In this trial, we observed that periprocedural administration of atorvastatin in high doses for a short duration, reduced the incidence of CI-AKI.

#3436

Efficacy of Adjunct Hemoperfusion Versus Standard Medical Therapy on 28-Day Mortality in Leptospirosis Patients with Renal Failure and Shock

Danice Romagne Leano, Romina Danguilan, Melhatra Arakama, Eric Chua, Vincent Apelin and Paolo Pinkerton Alamillo

National Kidney and Transplant Institute, Adult Nephrology, Quezon City, The Philippines

Background and Aims: Leptospirosis, a ubiquitous zoonotic infection in the Philippines, is a classic representation of sepsis-induced multi-organ dysfunction with its life-threatening complications: pulmonary hemorrhage, renal and liver failure. Despite pre-established treatment guidelines, leptospirosis-induced morbidity and mortality continue to rise. Hemoperfusion with HA 330 is a promising adjunct therapy as it removes rogue cytokines responsible for the dysregulated inflammatory response in severe sepsis. However, studies on its survival benefit have yielded conflicting results, so far. This study was designed to assess the efficacy and safety of hemoperfusion among leptospirosis patients in septic shock and renal failure, in terms of improvement in 28-day mortality, SOFA score, level of inflammatory markers, hemodynamics, renal and pulmonary function.

Method: This is an open-label randomized controlled trial which enrolled a total of 37 adult presumptive leptospirosis patients with early signs of septic shock and acute renal failure. The study participants were randomized into either of the two treatment arms: 1. standard medical therapy (SMT) alone or 2. SMT + HA330 Hemoperfusion (HP). All patients were managed based on the NKT Leptospirosis treatment protocol (hydration, antibiotics, three-day steroid pulsing, single cyclophosphamide dose and respective organ support) and were placed on daily intermittent hemodialysis. Subjects randomized to the HP group received three hemoperfusion sessions (on top of SMT). Vital signs, urine output, vasopressor dose, P/F ratio and biochemical parameters (including level of inflammatory markers) of patients from each treatment arm were measured at baseline, day 3 and day 7 and compared subsequently. Monitoring of participants continued until 28 days post-randomization. Descriptive statistics was used to summarize the general and clinical characteristics of the participants. Independent Sample T-test, Mann-Whitney U test, and Fisher's Exact/Chi-square test was used to determine the difference of mean, median and frequency between hemoperfusion group and control group, respectively. Mean, median, or risk difference and their corresponding 95% confidence intervals were calculated. Friedman test or Kruskal-Wallis test was used to determine whether differences between groups were significant over time. Intention to treat and per protocol analyses were performed. Null hypothesis was rejected at 0.05alpha-level of significance. Stata 15.0 (StataCorp LLC, TX) was used for data analysis.

Results: Hemoperfusion conferred a 36.84% (p = 0.017) risk reduction in 28-day mortality. Serial monitoring of inflammatory markers and SOFA score of patients showed significant improvement in sepsis score (p = 0.018 HP, 0.002 SMT) and levels of procalcitonin (p = 0.013 HP, 0.003 SMT), IL6 (p = 0.033 HP, 0.020 SMT) and lactate (p < 0.001 HP, 0.021 SMT) in both treatment arms, from baseline to Day 7. There is, however, no statistically significant difference in the change in SOFA (p = 0.965) and inflammatory marker levels if we compare HP versus SMT (p = 0.997, 0.451, 0.858, 0.052 for hsCRP, procalcitonin, IL6 and lactate, respectively). Statistically significant improvement in serum creatinine (p = 0.04) and PF ratio (p = 0.045) were observed in the hemoperfusion cohort as early as Day 3. Vasopressor dose did not differ significantly between two groups (p = 0.792). No adverse events were observed in both treatment arms.

Conclusion: Hemoperfusion is a safe and effective adjunct therapy in managing severe sepsis. It promotes earlier renal and pulmonary function recovery and, in doing so, improves survival of septic shock patients.

ACUTE KIDNEY INJURY (AKI) IN CANCER PATIENTS TREATED WITH COMBO THERAPIES: CHEMOTHERAPY, OR IMMUNOTHERAPY, THAT IS THE QUESTION

Marta Pirovano1, Giulia Vanessa Re Sarto1, Nico La Verde2, Annalisa Bramati2, Laura Cosmai1 and Maurizio Gallieni1,3

1 ASST Fatebenefratelli Sacco, Nephrology and Dialysis, Milan, Italy, 2 ASST Fatebenefratelli Sacco, Clinical Oncology, Milan, Italy and 3 University of Milan, Department of Biomedical and Clinical Sciences, Milan, Italy

Background and Aims: Lung cancer is the second most common malignancy in men and the third in women and approximately 85% of all cases are constituted by non-small cell carcinoma (NSCLC). In recent years, the introduction of immune checkpoint inhibitors and molecular targeted therapies, as monotherapy or in association with chemotherapy, has revolutionized the treatment of NSCLC. Pembrolizumab in association with pemetrexed and carboplatin, for instance, has been approved as first-line treatment for non-squamous NSCLC. Nephrotoxic side effects of both old and new therapies continue to be a substantial adverse event (AE) and could preclude effective oncological treatment. When a patient in combined oncological therapy develops AKI it is not always easy to establish which drug is responsible of the AE. The objective of our study was to develop a diagnostic algorithm to help the clinician to diagnose and manage AKI in patients treated with pembrolizumab + pemetrexed +/- carboplatin.

Method: We performed a retrospective multicentric data collection. We analyzed data about all the patients referred to the onconephrology outpatient clinic due to AKI (Stage 2 or higher) during oncological treatment with pembrolizumab + pemetrexed +/- carboplatin, from 2020 to 2022.

AKI stages were identified according to KDIGO guidelines and CTCAE 5.0. We focused on the following data: chemical-physical urinalysis, urinary electrolytes, serum electrolytes, kidney function (AKI progression and trend of renal function after oncological drug discontinuation).

Results: A cohort of 89 patients was analyzed: 54 males (61%) and 35 females (39%), with an average age of 69 years (51-76). The main comorbidities were hypertension (76%), diabetes mellitus (36%), CKD (64%) and cardiovascular diseases (26%). Overall, 11 patients (12%) had a non drug-related AKI, 90% of which due to pre-renal causes. 43 patients developed immune-related AKI; among these 23 pts had sterile pyuria and/or WBC casts, 35 pts had other organ IrAEs, 32 pts had AKI progression upon discontinuation of oncological therapy, and 37 pts had an increase in serum creatinine ≥ 1 mg/dl between two consecutive pretherapy blood tests.Chemotherapy-induced nephrotoxicity occurred in 35 patients and had the following features: hypo K or hypo Mg in 9 pts, increased urinary electrolytes in 16 pts, stable renal function after oncological drugs discontinuation in 32 pts and an increase in serum creatinine ≤ 0,5 mg/dl between two consecutive pretherapy blood tests in 27 pts. Characteristics of drug-related AKI are summarized in Table 1.

Conclusion: One of the main challenges with patients on multiple cancer therapies who develop AKI is to identify the possible drug responsible for the nephrotoxicity to avoid unnecessary suspension of one or more oncological drugs. Although the most frequently suggested approach is the execution of the renal biopsy, it is not always possible to perform it in a short time due to difficulties in organizing the diagnostic procedure and the time necessary for the histological analysis. Furthermore, Oncological Guideline recommend starting steroid therapy as soon as the Grade ≥2 immune related AEs develop. The above retrospective results shed light on the main characteristic of AKI due to immunotherapy or chemotherapy; the information obtained helped us to develop a diagnostic algorithm that addresses the clinician in identifying with reasonable certainty the cause of AKI without the need to perform a renal biopsy (Figure 1).

KIM-1, IL-18 AND NGAL IN MACHINE LEARNING PREDICTION OF KIDNEY INJURY AMONG CHILDREN UNDERGOING HEMATOPOIETIC STEM CELL TRANSPLANTATION

Kinga Musial¹, Jakub Stojanowski², Krzysztof Kalwak¹ and Marek Ussowicz³

¹Wroclaw Medical University, Department of Pediatric Nephrology, Wroclaw, Poland, ²Wroclaw Medical University, Department of Nephrology and Transplantation Medicine, Poland and ³Wroclaw Medical University, Department of Bone Marrow Transplantation, Oncology and Pediatric Hematology, Poland

Background and Aims: Children undergoing allogeneic hematopoietic stem cell transplantation (alloHSCT) are particularly vulnerable to acute kidney injury (AKI), especially in the early post-transplantation period. The major risk factors of AKI development are aggressive immunosuppression and infectious complications. In the meantime, malnutrition and hypermetabolic state of the patient, together with the routine intensive hydration during first 3 weeks after HSCT and subsequent forced diuresis, alter the serum creatinine concentration, modifying the estimated glomerular filtration rate (eGFR) value too. Therefore, the risk of underrating serum creatinine and overrating eGFR values is high, making the assessment of the degree of kidney damage during the first month after HSCT a challenge. Therefore, markers of tubular dysfunction and damage, like kidney injury molecule (KIM)-1, neutrophil gelatinase-associated lipocalin (NGAL) or interleukin (IL)-18, may be of added value while assessing renal function and analyzing the risk of AKI in this population. The aim of study was to assess the serum concentrations of damage biomarkers (KIM-1, NGAL, IL-18) in children undergoing alloHSCT, in relation to another surrogate marker of renal dysfunction, hyperfiltration. Another aim was to analyze the potential value of KIM-1, NGAL, and IL-18 as predictors of kidney damage in children after alloHSCT, with the use of artificial intelligence tools.

Method: The study group contained 22 children undergoing alloHSCT, followed up for 4 weeks after transplantation. Serum concentrations of KIM-1, NGAL, and IL-18 were assessed by ELISA in fixed time points (before HSCT, 1 day after HSCT, 1, 2, 3, 4 weeks after transplantation). eGFR values (counted based on Schwartz formula) and the rate of hyperfiltration (eGFR > 140ml/min/1.73sq.m.) were evaluated at the beginning (before HSCT) and at the end (4 weeks after HSCT) of observation, when neither hydration nor diuretics were used. Statistical analysis was performed with the use of package Statistica, the comparisons between paired data were evaluated by using nonparametric tests (Friedman, Wilcoxon). Additionally, the patients within the database were randomly divided into two groups. The training group allowed to build a Random Forest Classifier (RFC) with the highest possible predictive power, while the testing group allowed to assess the effectiveness of prediction on new data and the clinical utility. Moreover, the contribution of individual variables was evaluated by GINI importance.

Results: KIM-1, NGAL, and IL-18 serum concentrations increased systematically until the 3rd week after HSCT, with statistically significant differences between subsequent observation points, then remained elevated until the 4th week after HSCT. Median eGFR values before transplantation and 4 weeks after HSCT were comparable, although the rate of patients with hyperfiltration increased. The RFC model built on the basis of 3 input variables, KIM-1, NGAL, and IL-18 concentrations in serum of children before HSCT, was able to effectively assess the rate of patients with hyperfiltration 4 weeks after the procedure. RF Classifier achieved AUROC of 0.8333, accuracy of 80.00%, positive predictive value of 0.8667, and sensitivity of 0.8000. The contribution of KIM-1, IL-18 and NGAL to the prediction in this model was comparable (33.73%, 32.77%, and 33.5%, respectively).

Conclusion: KIM-1, NGAL, and IL-18 are useful in assessing acute tubular damage in children after HSCT. Their values before HSCT may also serve as markers of incipient renal dysfunction 4 weeks after alloHSCT. The developed model seems a clinically useful tool to target patients who are at risk of kidney injury after HSCT. The Random Forest Classifier seems a promising tool for such analysis, that should be tested on a larger group of patients.

EXTRACORPOREAL BLOOD PURIFICATION DURING OPEN HEART SURGERY WITH PROLONGED CPB: CYTOSORB 300 VS JAFRON HA330

Nilufar Jabayeva, Bolat Bekishev, Timur Lesbekov, Rymbay Kaliev, Zhuldyz Nurmykhameytova, Tatyana Li and Aidyn Kuanyshbek

National Research Cardiac Surgery Center, Astana, Kazakhstan

Background and Aims: Cardiac surgery is maintained by various complications. Major contribution associated with cardiopulmonary bypass (CPB).
Cardiac surgery with CPB provokes activation of the cascade mechanism of inflammation with releasing of cytokines and a systemic inflammatory response syndrome (SIRS). Activation of the contact system due to exposure of artificial surface of the bypass circuit to blood cells, endotoxemia, ischemia and reperfusion injury and surgical trauma are all potential triggers of inflammation following CPB. This inflammatory reaction may lead to the development of postoperative complications, including vasoplegia, cytokine storm, myocardial dysfunction, respiratory failure, acute kidney injury, and reperfusion injury and surgical trauma are all potential triggers of inflammation following CPB. This inflammatory reaction may lead to the development of postoperative complications, including vasoplegia, cytokine storm, myocardial dysfunction, respiratory failure, acute kidney injury, coagulopathy bleeding, and multiple organ dysfunction syndrome (MODS).

A number of different strategies, including new pharmacologic agents, CPB circuits and components, and surgical techniques, have been employed during the last few years in attempts to minimize the impact of SIRS on the outcome of cardiac surgical patients. However, the complex pathophysiology of this problem has not allowed, until now, the use of a single strategy. The aim of our study is assessment of early application of extracorporeal cytokine adsorbers to the inflammation system during open-heart surgery with prolonged cardiopulmonary bypass.

Method: This prospective randomized single-center controlled trial observed this prospective randomized single-center controlled trial observed this prospective randomized single-center controlled trial observed this prospective randomized single-center controlled trial observed this prospective randomized single-center controlled trial observed this prospective randomized single-center controlled trial observed this prospective randomized single-center controlled trial observed.

Results: The data of the HA 330 (n = 22) and CytoSorb300 (n = 22) groups were compared with the data of the control group (n = 22). The primary results and details of the work are given in Tables 1-3.

Conclusion: Intraoperative hemadsorption may be beneficial for patients who underwent open-heart surgery with prolonged CPB. The early hemadsorption has positive impact to postoperative period after cardiac surgery and may reduce requirement of renal replacement therapy.
of selective extracorporeal elimination can prevent the development of irreversible renal failure and make it possible to carry out adequate antitumor therapy.

#6030 CARDIAC ULTRASOUND ASSESSMENT AND THE NOVEL INFLAMMATION, FIBROSIS AND CALCIFICATION BIOMARKERS IN ESKD PATIENTS ON HD THERAPY: A PILOT STUDY

Adalbert Schiller1,2,3, Flavin Bob1,2,3, Adelina Mihaescu1,2,3, Lazar Chisavs1,2,3, Luciana Marc1,2,3, Adelina Mihaescu1,2,3, Raluca Lupusoru 3 and Viviana Ivan 6

Background and Aims: Novel biomarkers for inflammation, fibrosis, and vascular calcification have been recently used for further assessment of cardiovascular risk. The aim of our prospective study is to assess the relation between the novel cardiovascular biomarkers and biomarkers for vascular calcification with cardiac ultrasound function/morphology alteration in high cardiovascular risk patients with end stage kidney disease (ESKD) on haemodialysis (HD) therapy. Baseline findings are discussed in this pilot paper.

Method: The study included 58 ESKD patients [55% men, mean age of 60.3 ± 11.7 years, and median hemodialysis therapy duration of 6.2 years (1.2 - 25.7)], treated with HD (3 sessions of 4 hours /week with high flux dialyzers). Personal and laboratory data have been retrieved from the patients HD files. Cardiac ultrasound assessment was performed during the second HD session of the week, after 2 hours of HD therapy. Blood samples have been taken before the same HD session in order to determine FGF 23, BMP 2, IL 1 beta, Galectin 3 and soluble ST 2 levels. All patients signed an informed consent for the study participation and the use of personal and laboratory data for scientific purposes. The study was approved by the medical ethics committee of the "Victor Babes" University of medicine and pharmacy and of the ethics committee of the HD center.

Results: On cardiac ultrasound assessment the patients presented aorta atheroma in 74.1%, aorta valve fibrosis in 74.1%, mitral valve fibrosis in 74.1% of the cases. Calcifications have been evidenced at aorta valve level in 58.6%, mitral valve level in 75.8% and endocardial valve level in 67.2% of the cases. Increased left ventricular mass was present in 82.7%, enlarged interventricular septum in 74.1% of the cases. Decreased left ventricle diastolic filling (Appleton pattern - E/A) was evidenced in 55.1% of the cases and decreased left ventricular ejection fraction in 37.9%. Right ventricle enlargement was detected in 24.1% of the patients. At baseline, FGF 23 was inversely correlated with serum albumin levels and inversely with left ventricle diastolic filling (E/A) (p < 0.05). IL1 levels were inversely correlated with iPTH (p = 0.046), calcium (p = 0.046 and phosphate (p = 0.030) levels but not with the ultrasound findings. BMP 2 levels correlated directly with serum albumin levels and inversely with left ventricle diastolic filling (E/A) (p < 0.05). IL1 levels were inversely correlated with iPTH (p = 0.046), calcium (p = 0.046 and phosphate (p = 0.030) levels but not with the ultrasound findings. Galectin 3 inversely correlated with cu Hb (p = 0.002), Urea (p = 0.036) and K levels (p = 0.001) and directly with bicarbonate (p = 0.035), FGF 23 (p < 0.05) and CRP levels (p<0.0001), ST2 inversely correlated with ESA dose (p = 0.009) and decreased left ventricle diastolic filling (E/A) (p < 0.05). At one year follow-up 12% of the patients died and mortality was significantly influenced by inter ventricle sept and right ventricle enlargement.

Conclusion: At baseline, though the investigated ESKD patients on HD therapy presented extensive cardiac valve fibrosis and heart valve and endomyocardial calcifications the investigated biomarker changes were not significantly supporting the ultrasound findings. One- and two-years follow-up results may reveal the utility of biomarker assessment for cardiovascular outcomes in HD treated ESKD patients.

#2634 ROLE OF LIGHT CHAIN CLEARANCE IN THE RECOVERY OF RENAL FUNCTION IN MULTIPLE MYELOMA: ANOTHER POINT OF VIEW

Marc Patricio Liébana1,2, Alicia Senín2,3, María Azancot4, Mercedes Gironella3, Néstor Toapanta Gaiboe1, Sheila Bermejo García2, Lucia Martín1, Fernando Caravaca-Fontán1, Clara Cuéllar Pérez-Ávila1, Joaquín Martínez-López2, Eva Rodríguez-Garcia6, Oriol Bestard Matamoros1, María José Soler Romeo1 and Natália Ramos Torreses1

1 Hospital Universitari Vall d’Hebron, Nephrology, Barcelona, Spain, 2 Institut Català d’Oncologia - Hospital Duran i Reynals, Hematology, L’Hospitalet de Llobregat, Spain, 3 Hospital Universitari Vall d’Hebron, Hematology, Barcelona, Spain, 4 University Hospital October 12, Department of Nephrology, Madrid, Spain, 5 Hospital Universitario de Bellvitge, Nephrology, Barcelona, Spain and 6 Hospital del Mar, Nephrology, Barcelona, Spain

Background and Aims: Acute Kidney Injury (AKI) in patients with multiple myeloma (MM) requiring renal replacement treatment (RRT) is associated with high morbidity and mortality. Early reduction of serum free light chains (FLC) using both targeted therapy against MM and intensive hemodialysis (IHD) may improve renal outcomes. We evaluated the effectiveness of two different RRT techniques on renal recovery in a MM patient population: standard dialysis procedure versus IHD with either PMMA or hemodiafiltration with endogenous reinfiltration (HFR).

Method: Multicentric retrospective study with severe AKI related to MM, between 2011 and 2018. Twenty-five consecutive patients with AKI secondary of MM requiring RRT were included. Patients that underwent IHD received 6 dialysis sessions per week during the first 14 days (PMMA vs HFR). All patients were diagnosed with de novo MM or first relapsed MM. Primary outcome was renal recovery defined as dialysis-free at six months follow-up.

Results: A total of 25 patients were included. Seventeen patients received IHD and standard dialysis. All patients were treated with targeted therapy. 84% bortezomib-based. Of the 25 patients included, fourteen (56%) became dialysis independent. We observed a higher proportion of patients who received IHD in the group who recovered kidney function compared to those who remained in HD (92.9% vs 36.4%, p=0.007). In our study, the use of IHD to remove FLC had a statistically significant association with renal recovery compared to standard dialysis group (p = 0.024).

Conclusion: Early reduction of FLC with IHD as an adjuvant treatment along with MM targeted therapy may exert a positive impact on renal recovery.

#4733 NEFROTOXICITY CAUSED BY COLISTIN USE: A SINGLE CENTER EXPERIENCE

İsa Kılıç1, Yavuz Ayar2, İlay Ceylan3, Pinar Kucukdemirci Kaya4 and Gulbahar Caliskan5

1 University of Health Sciences, Faculty of Medicine, Bursa City Hospital, Anesthesiology and reanimation, Bursa, Turkey, 2 University of Health Sciences, Faculty of Medicine, Bursa City Hospital, Nephrology, Bursa, Turkey, 3 University of Health Sciences, Faculty of Medicine, Yuksek Ihtisas Training and Research Center, Anesthesiology and reanimation, Intensive Care Unit, Turkey and 4 University of Health Sciences, Faculty of Medicine, Bursa City Hospital, Anesthesiology and reanimation, Intensive Care Unit, Bursa, Turkey

Background and Aims: In resistant infections and septic patients, the choice of colistin in the selection of antibiotic therapy is important in the treatment response. Kidney damage is common after antibiotic use. In our study, we evaluated the clinical and laboratory data of the patients who developed nephrotoxicity after the use of colistin, followed in the intensive care unit of our hospital.

Method: The clinical and laboratory characteristics and treatment results of 148 patients (54 nephrotoxic patients) with infection who were followed up in the intensive care unit (ICU) of our hospital evaluated.

Results: The group that developed nephrotoxicity was older [70.5 (40-91), p<0.001]. The APACHE II score was higher in the nephrotoxicity group [20.5 (5-49), p = 0.004]. Positive inotrope use and mortality were higher in the nephrotoxicity group [32 (59.3%), p<0.001 and 30 (55.6%), p = 0.004]. The duration of colistin use was longer in the nephrotoxicity group [13.5 (3-36), p = 0.045]. In the group that developed nephrotoxicity, the highest growth was detected in the tracheal aspirate (TAS) [49 (90.7%), p = 0.045]. Positive inotrope use and growth in TAS culture predisposed the development of nephrotoxicity in multivariate analysis [3.12 (1.38-7.02), CI 95%, p = 0.006, 5.70 (1.64-19.79), CI 95%, p = 0.006].
Background and Aims: This difference can be expressed in absolute terms (mL/min) or relative terms between the stimulated glomerular filtration rate (GFR) and the baseline GFR.

Conclusion: Consideration should be given to the use of colistin in resistant infections and septic patients in terms of nephrotoxicity and mortality. Antibiotic selection should be considered in critically ill patients, and patients should be closely monitored.

THE EVALUATION OF RENAL FUNCTIONAL RESERVE WITH ORAL PROTEIN LOAD OR ULTRASOUND TEST: A REAL-LIFE PERSPECTIVE

Nicoletta Mancianti1, Andrea Guarneri2, Guido Garosi3, Massimo Belluardo4 and Ernesto Iadanza5

1 University Hospital of Siena, Siena, Italy, Department of Emergency-Urgency and Transplantation, Nephrology, Dialysis and Transplantation Unit, Siena, Italy, 2University Hospital of Siena, Siena, Italy, Department of Emergency-Urgency and Transplantation, Nephrology, Dialysis and Transplantation Unit, Monteriggioni, Italy, 3University Hospital of Siena, Siena, Italy, Department of Emergency-Urgency and Transplantation, Nephrology, Dialysis and Transplantation Unit, Italy, 4University Hospital of Siena, Siena, Italy, Stem Cell Transplant and Cellular Therapy Unit, Italy and 5Department of Information Engineering, University of Florence, Italy

Background and Aims: The RFR (renal functional reserve) is the difference between the stimulated glomerular filtration rate (GFR) and the baseline GFR. This difference can be expressed in absolute terms (mL/min) or relative terms (percentage of increment relative to the baseline GFR). This index makes it possible to highlight a subclinical renal functional deterioration when the laboratory values of creatinine are still within the normal range. Measurement of RFR by protein load (1 g/kg of oral protein) (RFR-T) is now considered the gold standard for RFR assessment. RFR measured with protein load (RFR-T) predicts the risk of acute kidney injury (AKI) or chronic kidney disease (CKD) in both healthy and diseased patients and is particularly useful in patients with apparently normal renal function before stress candidate for interventions at real risk of renal failure (kidney donors, cardiac surgery, bone marrow transplants). However, the protein load test has a long duration (about 5 hours), requires numerous blood and urine samples, and is challenging to use on a large scale. Recent studies have proposed another method based on the variation of the renal intraparenchymal resistance index (IRRIV-T). In this case, the stress to which the kidney is mechanical. That is a weight (saline bag, representing 10% of the body weight) placed on the abdomen of the supine patient, which induces maximal renal vasodilation. The sampling of the intraparenchymal resistance doppler indices before and after the weight application would correlate, in preliminary studies, with the RFR tested with the protein load. Thus, offering a fast and non-invasive method. Eventually, comparing these divergent diagnostic procedures can guide us in choosing the most cost-effective approach to gain deeper insight into renal health. (Fig. 1)
Exclusion criteria were: (i) non-steroidal inflammatory drugs (NSAIDs), (ii) ultrasound evidence of renal morphological changes or artery stenosis. Each patient underwent oral protein load testing (RFR-T) and an ultrasound test (IRRIV-T). Pearson’s correlation index analyzed the comparison between the 2 tests.

**Results:** There was no statistically significant correlation between RFR-T and IRRIV-T in terms of the RFR either in absolute numbers ($R = 0.14$, $p = 0.37$) or in percentage values ($R = 0.15$, $p = 0.33$). (Fig. 2) Based on our experience, the IRRIV test proved unreliable in evaluating RFR compared with the gold standard (RFR-T). Therefore, not suitable to be used as a possible alternative to the oral protein load test.

**Conclusion:** Unlike previous studies, our survey is a real-life study. Many of our patients have pathologies or take drugs that could alter the hemodynamic and the renal vascular response, consequently changing the outcome of the IRRIV test. However, it is a real-life experience that aims to offer a practical point of view, bringing to light the possible limitations of the ultrasound test when applied to a standard evaluation population and not to a healthy or highly selected population as in the only three previous works published in the literature up to now. Our work is the first original real-life study in this field.

**DRUG-INDUCED ACUTE INTERSTITIAL NEPHRITIS (D-AIN): HOW TO IDENTIFY THE RESPONSIBLE DRUG?**

Javier Azores Moreno1, Begoña Rivas1, Cristina Vega Cabrera1, Rosario Cabañas2, Eugenia García Fernández3, Laura Yébenes1, Sara Aldana Barceló1, Irene Vázquez Raso1 and Gema Maria Fernandez Juárez1

1Hospital Universitario La Paz, Nephrology, Madrid, Spain, 2Hospital Universitario La Paz, Allergology, Madrid, Spain and 3Hospital Universitario La Paz, Pathological Anatomy, Madrid, Spain

**Background and Aims:** The mainstay of D-AIN treatment is the removal of the responsible drug. However, it is not always easy to identify the culprit drug as this entity mainly affects elderly patients on multiple medications, they rarely associate systemic symptoms (rash, fever), and the timeline regarding the diagnosis and the associated drug is not always clear. Therefore, the diagnosis and treatment are delayed, making full renal function recovery less likely. The lymphocyte transformation test (LTT) has demonstrated to be useful in the identification of the involved drug in other hypersensitivity-mediated lymphocyte T diseases such as Stevens-Johnson Syndrome or Dress Syndrome. For this reason, we wonder if this test could be relevant in identifying the responsible drug in D-AIN. The aim of this study is to test LTT in patients with clinical and histological diagnosis of D-AIN.

**Method:** We have conducted a retrospective observational study in which we have collected data from 2019 to 2022 from our electronic databases.

**Results:** We have registered 9 cases of D-AIN diagnosed with histological confirmation in whom the LTT had been performed. 22.2% of these patients were men. The mean age was 48.1 years (standard deviation of 15.8). None of them had previous chronic kidney disease (CKD). Mean peak creatinine at diagnosis was 4.66 mg/dl (standard deviation of 1.95). Regarding the typical symptoms of the D-AIN, three patients (33%) presented with fever and none of them suffered from rash. 6 patients had sterile pyuria (66%). All of them received steroid treatment. Concerning the LTT results, 7 cases were positive for one of the drugs the patient was taking, and 2 were negative. Among the positive cases, the identified drugs were 1 case of beta lactams (piperacillin), 1 case of PPIs (omeprazole), 1 case of metamizole, 1 case of paracetamol, 1 case of eslicarbazepine and 2 cases of NSAIDs (dextropropofen), while the negative cases have not been suspected of taking any culprit drug.

**Conclusion:** LTT may be a useful test to identify the responsible drug for D-AIN, especially in patients taking multiple medications in which may be included some of great importance like immunotherapy (typical cause of D-AIN) in oncological treatments. In negative cases, it could be expected that the patient had taken medications difficult to be identified in the clinical history or, in some situations, the drug hapten responsible for kidney damage might be a drug metabolite and not the drug itself, which cannot be detected by the test.

### DIAGNOSTIC AND THERAPEUTIC IMPACTS OF AIM ON END-STAGE KIDNEY DISEASE

Toru Miyazaki and Satoko Arai

The Institute for AIM Medicine, Tokyo, Japan

**Background and Aims:** End-stage kidney disease (ESKD) is life-threatening, and indispensably requires dialysis which however imposes huge burdens on patients’ QOL and medical expense. No therapies to prevent CKD progression to the end-stage have reached clinic to date. Patients undergoing dialysis exhibit a high mortality mainly due to cardiovascular diseases (CVDs), but no biomarkers are available to predict the patients’ death and the incidence of cardiovascular disease (CVD), the major cause of death, before initiation of dialysis. AIM is a macrophage-derived circulating protein present in blood at relatively high levels (~5 μg/mL). We initially identified AIM as a supporter of macrophage survival, and it is now known as a facilitator of repair in many diseases. In healthy state, AIM associates with IgM pentamer through disulfide-bond formation and charge-based interaction with IgM-Fc, using the solitary cysteine residue and the positively charged-amino acid cluster present at the carboxyl-terminal. During various diseases including acute kidney injury, hepatocellular carcinoma and peritonitis, AIM dissociates from IgM and binds to the body-derived types of inflammatory elements using the identical sites necessary for binding to IgM, thereby promoting their phagocytic removal by phagocytes.

**Method:** In 561 CKD patients of all stages and 310 dialysis patients, we analyzed the serum AIM and the serum solute profiles, and thereby assessed their efficacy in predicting survival and CVD risk after dialysis induction. Additionally, a therapeutic efficacy of recombinant AIM (rAIM) in preventing CKD progression to end-stage was addressed in house cats, that are highly susceptible to CKD and show a similar disease course to humans.

**Results:** AIM dissociated from IgM pentamer along CKD progression. Dialytic patients showing low levels of AIM dissociation before initiation of dialysis harbored less serum detrimental solutes, exhibited lower risk of CVD and had better survival than those with high grades of AIM dissociation, suggesting that the IgM-free AIM represents the state of serum toxic solutes, and predicts patients’ prognosis before initiation of dialysis. In addition, treatment of pre-uremic (late IRIS stage 3) cats, 50% of which died of severe uremia within 196 days after diagnosis, with recombinant AIM prevented aggravation of renal function and inflammation, as well as serum toxic solute profile, thereby improving the cats’ survival dramatically. Importantly, the same serum toxin/inflammatory solutes regulatable by rAIM in cats influenced dialysis patients’ prognosis.

**Conclusion:** There results promise the effects of AIM treatment in humans, reducing the need for dialysis. Our findings could be a platform for new CKD therapies and predictive diagnoses to improve the prognosis of patients with ESKD.

### IV IRON IN CKD AND HF: IMPROVING CLINICAL OUTCOMES WITH HIGH-DOSE IV IRON IN PATIENTS WITH IRON DEFICIENCY, HEART FAILURE AND CKD

Philip A. Kalra and Foizia Ahmed

NHS Nightingale Hospital Exeter, United Kingdom

**Background and Aims:** The emerging role of IV iron to reduce cardiovascular risk, particularly risk of hospitalisation for heart failure. Cardiovascular diseases are a common comorbidity in patients with chronic kidney disease. There is emerging evidence that treating with IV iron may not only correct for iron deficiency and anaemia but also have positive effect on hard clinical endpoints.

**Method:** The most recent RCT trial published is the IRONMAN trial, which was a prospective, randomised, open-label, blinded-endpoint trial done at 70 hospitals in the UK. 1137 patients with heart failure, a reduced left ventricular ejection fraction and iron deficiency were randomised to receive either ferric derisomaltose (FDI) on top of usual care or usual care alone. A large proportion of the patients (64%) had an eGFR < 60 mL/min/1.73 m².

**Results:** Compared to usual care, FDI was associated with a 18% lower risk of recurrent heart failure hospitalisations and CVD death, which approached statistical significance (p = 0.07). In the prespecified COVID-19 sensitivity analysis, the primary endpoint was nominally statistically significant with a relative risk reduction of 24% (p = 0.047). Between Aug 25, 2016, and Oct 15, 2021, 1869 patients were screened for eligibility, of whom 1137 were randomly assigned to receive intravenous ferric derisomaltose (n = 569) or usual care (n = 568). Median follow-up was 2.7 years (IQR 1.8–3.6). 336 primary endpoints (22.4 per 100 patient-years) occurred in the ferric derisomaltose group and 411 (27.5 per 100 patient-years) occurred in the usual care group (rate ratio [RR] 0.82 [95% CI 0.66 to 1.02]; p = 0.070). In the COVID-19 analysis, 210 primary endpoints (22.3 per 100 patient-years) occurred in the ferric derisomaltose group compared with 280 (29.3 per 100 patient-years) in the usual care group (RR 0.76 [95% CI 0.58 to 1.00]; p = 0.047). No between-group differences in deaths or hospitalisations due to infections were observed. Fewer patients in the ferric derisomaltose group had cardiac serious adverse events (200 [36%]) than in the usual care group (243 [43%]; difference −7.00% [95% CI −12.69 to −1.32]; p = 0.016).

**Conclusion:** For a broad range of patients with heart failure, reduced left ventricular ejection fraction and iron deficiency, intravenous ferric derisomaltose administration was associated with a lower risk of hospital admissions for heart failure and cardiovascular death, further supporting the benefit of iron repletion in this population.

Figure 1:
Upar Activation by Uparan Induced Functional and Structural Recovery of Podocytes After FSGS-Serum Damage

Deborah Mattinzoli, Silvia Armelloni, Min Li, Daniele Dalonzo, Maria Defenza, Masami Ikehata, Carlo Maria Alfieri, Vincenzo Pavone and Giuseppe Castellano

1 Fondazione IRCCS Ca’ Granda Ospedale Maggiore Policlinico, Renal Research Laboratory, Milan, Italy, 2 Fondazione IRCCS Ca’ Granda Ospedale Maggiore Policlinico, Milan, Italy, 3 University of Naples ‘Federico II’, Department of Chemical Sciences, Naples, Italy, 4 Fondazione IRCCS Ca’ Granda Ospedale Maggiore Policlinico / University of Milan, Unit of Nephrology, Dialysis and Renal Transplant, Department of Clinical Sciences and Community Health, Italy and 5 Fondazione IRCCS Ca’ Granda Ospedale Maggiore Policlinico / University of Milan, Unit of Nephrology, Dialysis and Renal Transplant, Department of Clinical Sciences and Community Health, Italy

Background and Aims: Idiopathic focal segmental glomerular sclerosis (FSGS) is characterized by progressive damage to the renal parenchyma leading to end-stage renal disease, frequent recurrence after kidney transplantation and no specific therapeutic intervention. Since the podocytes (PODO) are the principal target of FSGS injury, their protection could be an efficient, targeted therapy. In this context, we investigated a potential therapeutic approach based on a new peptide, UPARANT, capable of modulating the Urokinase-type plasminogen activator receptor (uPAR) on PODO.

Method: PODO were activated with 4% sera of 5 patients with recurrent FSGS for 48 h and then treated with 100 nM of UPARANT for 48 h. Proteins were then extracted for TMT proteomics. The Gene Ontology system database, valid for large-scale analysis, was used to identify the significantly enriched biological pathways and molecular functions. An in vitro model of a glomerular filtration barrier composed of PODO-endothelial co-culture was used to assess the change in filtration capacity by albumin (BSA) permeability test. The difference from baseline BSA percentage was measured after damage induced with sera from three FSGS patients and after 48 h of treatment with UPARANT.

Figure 1: Overall distribution of differentially expressed proteins Volcano plot in FSGS-sera PODO injury versus the same condition followed by UPARANT addition (A). Gene ontology analysis of all overexpressed proteins ranked by fold enrichment for biological process (B) and molecular function (C). n=4/group.

Figure 2: Albumin filtration capacity evaluation in the PODO-ENDO co-culture system after FSGS sera patient sera, and after sera followed by UPARANT treatment *=p<0.05, by Student’s t-test. n=3/group.

PROTECTIVE POTENTIAL OF 17-β-ESTRADIOL ON OXIDATIVE STRESS AND RENAL METABOLISM IN AGED FEMALE RATS

Pardeep Kumar
FH M college and hospital, Biochemistry, UP, India

Background and Aims: The objective of this study was to observe the changes in activity of antioxidant enzymes, hepatic glucose homeostasis, lipogenic enzymes and lipid metabolism, serum lipid profile and liver function occurring in livers of female rats of 3, 12 and 24 months age groups, and to see whether these changes are restored to 3 months control levels rats after exogenous administration of steroid hormone estrogens (17-β-estradiol, E2).

Methods: The aged rats (12 and 24 months old) (n= 8 for each group) were given subcutaneous injection of 17beta estradiol (0.1 ug/g body weight) daily for one month. After 30 days of hormone treatment, experimental animals of all the groups were sacrificed and livers were isolated for further study. A detailed study was carried on non-enzymatic glutathione (GSH) and enzymatic antioxidants [superoxide dismutase (SOD), glutathione peroxidase (GPX) and catalase (CAT)], hepatic glucose homeostasis, lipogenic enzymes, lipid metabolism, serum aspartate aminotransferase (GOT), alanine aminotransferase (GPT), alkaline phosphatase (ALP), gamma-glutamyl transferase (GGT), phosphatase alkaline (PAL) as well as bilirubin level.

Results: The results obtained in the present work revealed that normal aging was associated with significant decrease in the activities of antioxidant enzymes, serum expression and an increase in hepatic glucose homeostasis, lipogenic enzymes and lipid profile and GGT, PAL, GOT, ALP as well as bilirubin level increased significantly in livers of aging female rats. Our data showed that exogenous administration of E2 brought these changes to near normalcy in aging female rats.

Conclusions: The present study showed that E2 treatment reversed the changes to normal levels. E2 treatment may be beneficial in preventing some of the age related changes in the liver by increasing antioxidant defences and decrease oxidative stress. E2 plays important role in the progression of chronic hepatic diseases.

LUPUS NEPHRITIS: THE INTERPLAY BETWEEN SENESCENT B AND NAÏVE T LYMPHOCYTES

Eleni Moysidou1, Georgios Lioulous1, Michalis Christodoulou1, Aliki Xochelli2, Vasiliki Nikolaidou1, Stamatis Stai1, Asimina Fylaktou2, Aikaterini Papagianni1 and Maria Stangou1
1Aristotle University of Thessaloniki, Greece, Department of Nephrology, Hippokration Hospital of Thessaloniki, Greece, Thessaloniki, Greece and 2Hippokration Hospital of Thessaloniki, Department of Immunology, National Peripheral Histocompatibility Center, Greece, Thessaloniki, Greece

Background and Aims: Systemic Lupus Erythematosus (SLE) is characterized by a shift to senescent B cells, namely, switched memory (SM) (CD19+IgD-CD27+) and exhausted-double negative (DN) (CD19+IgD-CD27-) subtypes. The aim of this study was to evaluate the impact of T cell immunity in the distinct B cell - senescent pattern of SLE.

Method: A wide range of senescent and exhaustion related lymphocyte surface molecules, including CD45RA, CCR7, CD31, CD28, CD57, on T cells and CD27 and IgD on B cells, was analyzed by flowcytometry and distinct naïve, active and senescent B and T lymphocyte subtypes were determined in 31 patients with inactive Lupus Nephritis (LP).

Results: Comparison of SM and DN B cells with T cell subpopulations revealed significant correlation of naïve and “unexperienced” CD4 and CD8 compartment with SM and DN B cells. Indeed, the correlation appeared even stronger regarding SM B cells and Recent thymic emigrants (RTE) CD4CD31+ (r=0.575), CD4+ Central Memory (CM) (CD45RA-CCR7+) (r=0.546), CD4CD45RA+CD28+(r=0.556), CD4CD28+CD57- (r=0.621), CD4CD45+CD57- (r=0.544), CD4CD45+CD57- (r=0.65), CD8CD28+CD57- (r=0.596), CD8CD45+CD57- (r=0.556) while weak yet significant was their correlation with CD4 Naïve (CD45RA+CCR7+) (r=0.432), CD8CM (CD45RA+CCR7+) (r=0.474), RTE CD8CD31+ (r=0.461), CD8CD28+CD57- (r=0.442), Less apparent was this phenomenon between DN B cells and CD4 CM (CD45RA-CCR7+) (r=0.381), CD4CD45RA+CD28+ (r=0.504), RTE CD4CD31+ (r=0.587), CD8CD28+CD57- (r=0.487), CD8CD28+CD57+ (r=0.491), CD4CD45+CD57- (r=0.419), CD4CD45-CD57- (r=0.397), CD8 Naïve (CD45RA+CCR7+) (r=0.432), RTE CD8CD31+ (r=0.366), CD8CD28+CD57- (r=0.363), CD8CD28+CD57+ (r=0.483), CD8CD45+CD57- (r=0.444), CD8CD45-CD57- (r=0.384).

Conclusion: The predominant shift to senescent/exhausted B lymphocytes in SLE and LN may have a direct impact on naïve CD4 and CD8 T lymphocyte subpopulations.

A2 - RENAL DEVELOPMENT & MOLECULAR GENETICS

#5276

DEVELOPMENT OF A MULTIMODAL "KIDNEY AGE" PREDICTION BASED ON AUTOMATIC SEGMENTATION CT IMAGE IN PATIENTS WITH NORMAL RENAL FUNCTION

Zuxian Hou1, Gu-Mu-Yang Zhang2, Yixin MA1, Peng Xia1, Xiaoxiao Shi1, Hao Sun3, Zhengguang Chen1 and Limeng Chen1
1Peking Union Medical College Hospital, Department of Nephrology, Beijing, P.R. China, 2Dongzhimen Hospital, Beijing University of Chinese Medicine, Department of Radiology, Beijing, P.R. China and 3Peking Union Medical College, Department of Radiology, Beijing, P.R. China

Background and Aims: Renal function, for decades, has been of interest to clinicians and researchers to describe. For example, serum creatinine (Scr) and estimated glomerulus filtration rate (eGFR) is familiar but also limited in many circumstances. Meanwhile, the physiological volumes of the kidney cortex and medulla are presumed to change with age and have been proven to change with decreasing kidney function.

Method: We recruited 182 patients with normal Scr levels and contrasted CT images between Oct. 2021 and Feb 2022 in Peking Union Medical College Hospital (PUMCH) with their demographic and clinical data. The automatic segmentation method was modified from U-NET and used for both cortex and medullary separation and their volumecalculation, respectively. We combined the kidney volume and clinical data as multimodal features of the machine learning model. All the data were separated into a training dataset (PUMCH training set, 80%) and a test dataset (PUMCH test set, 20%). Besides, we included patients with the same inclusion criteria but with diabetes (PUMCH-DM test set) and diabetic nephropathy (PUMCH-DN test set) for internal comparison to verify the possible clinical value of “KIDNEY AGE” (K-AGE).

Data from DongZhiMen Hospital (DZMH test set) was used as separate external validation sets to evaluate model generalizability.

Results: The PUMCH training set included 146 participants with a mean age of 47.5±7.4 years. 58.9% were female, and the mean Scr is 63.5±12.3 μmol/L. The PUMCH test set included 36 participants with a mean age of 47.1±7.9 years, 52.7% were female, and the mean Scr was 66.9±13.0 μmol/L. For segmented kidneys, volume differences between non-contrast-enhanced CT and non-contrast-enhanced CT in the left and right kidneys were not evident. The multimodal network predicted: K-AGE approximately close to the patient’s actual physiological age, with 92% prediction within the 95% confidence interval (Figure 1). We also compared the K-AGE prediction in PUMCH, PUMCH-DM, and PUMCH-DN test sets by applying U-NET-nonCon segmentation algorithm in non-contrast CT images. The mean absolute error increases along with the disease process (control group 5.00, diabetes group 6.99, diabetic nephropathy group 9.32) (Figure 2).

Conclusion: We established a machine learning model for predicting the K-AGE of normal Scr patients.

GENETIC GLOMERULAR DISEASES IN THE ADULT PATIENT: A WORK IN PROGRESS – SINGLE CENTRE COHORT

Telma Pais1, Sofia Jorge1, Filipe Marques1, Sara Gonçalves1, José Agapito Fonseca1, Iolanda Godinho1, Estela Nogueira1, Joana Gameiro1,2, Márcia Rodrigues1, José António Lopes1,2

1Centro Hospitalar Universitário Lisboa Norte, Nephrology and Renal Transplantation, Lisboa, Portugal, 2Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal and 3Centro Hospitalar Universitário Lisboa Norte, Genetics, Lisboa, Portugal

Background and Aims: Recent advances in genetic molecular techniques have allowed the expansion of knowledge in glomerular diseases of genetic cause, including the identification of genes involved in focal and segmental glomerular sclerosis (FSGS). The prevalence of adult-onset genetic FSGS varies widely depending on the population studied. In central Europe, NPHS2 and COL4A3, COL4A4 e COL4A5 genes are postulated to be the most frequent genes implicated in genetic causes of adult FSGS. This study aims to characterize patients submitted to genetic study of glomerular diseases in the Nephrogenetics Clinic of our centre.

Method: We conducted a single-centre retrospective analysis of the patients submitted to genetic study of glomerular diseases in the Nephrogenetics Clinic of our centre from 2016 to 2022. Adult patients with a glomerular disease phenotype suggestive of a genetic cause were studied, using a predetermined phenotype-targeted panel of genes, through massive parallel sequencing. The number of genes included in this panel has increased (from 21 genes in 2016 to 49 genes since 2018); given this change, patients with a negative result on the first approach repeated screening with the broader panel. Additionally, patients presenting with advanced chronic kidney disease (CKD) without an identifiable phenotype, studied with a larger panel for CKD causing genes, are reported. In patients with a negative result but highly suggestive presentation, whole exome sequencing (WES) was considered, after multidisciplinary discussion with a Geneticist’s evaluation. Patients with variants of unknown significance (VUS) were referred to a Genetics’ consultation for genetic counselling and segregation studies.

Results: Of the 80 patients studied (comprising 74 families), 52.5% were female (n=42) and 79% (n=63) of Caucasian ascent. Mean age was 45.4 ± 16.0 years. Nine patients were studied with the larger gene panel for CKD. 85% (n=68) had CKD (all stages) at presentation, with proteinuria (ranging from sub-nephrotic to nephrotic range) and 15% had asymptomatic urinary changes. 50% (n=40) of patients had positive family history, and 31% (n=25) had a syndromic presentation and/or extra renal manifestations. 27.5% (n=22) had a renal biopsy, and the most prevalent result was FSGS (11%; n=9). Genetic variants were identified in 70% (n=56) of the patients; but pathogenicity is not fully established in all: genotype-phenotype correlations, including inheritance pattern and histological correlation, and segregation studies (when indicated and possible) are ongoing. In 5 patients results are pending. Pathogenic / likely pathogenic variants were identified in at least 47.5% (n=38) patients. The most frequently implicated genes were: COLA3, COL4A4 e COL4A5 (n=21), high risk APOL1 (n=8); NPSH2 (n=5), IFN2 (n=6, 3 pathogenic, 1 variant of unknown significance (VUS), 2 under segregation studies) and MYH9 (n=3). COL4A3, COL4A4 e COL4A5 mutations occur with Alport syndrome, but also with histologically documented FSGS, sub-nephrotic and nephrotic proteinuria, nephrotic syndrome and asymptomatic urinary changes. In our
cohort, NPHS2 p.R229Q was identified in 5 patients (6%), but only with pathogenic significance in 3 patients, and APO1 high risk haplotype was co-identified with COL1 variants in 3 patients.

**Conclusion:** The genetic study of a cohort of patients suspected of genetic FSGS allowed the identification of genetic variants in the genes of interest in a high percentage of cases. The most frequently implicated genes were COL4A3, COL4A4 e COL4A5, NPHS2, INF2 and APO1 high risk haplotype. The high percentage of gene variants identified in our cohort is probably due to the selection of a population with a high likelihood of genetic FSGS. Further studies will clarify the causal and/or modifier effect of some genes, namely COL4A3, COL4A4 e COL4A5. The future use of WES in cases of high likelihood of genetic cause will probably allow the identification on novel candidate genes and increase the clinical benefits of a genetic diagnosis of FSGS.

**CLINICAL CASE OF MOSAICISM IN ADPKD PATIENT**

Nenzi Marzano1, Valentina Corradi2, Carlotta Caprara3, Matteo Rigato3, Anna Giuliani2, Fiorella Gastaldon2, Claudio Ronco1 and Monica Zanella2

1International Renal Research Foundation (IRRIV), Vicenza, Italy and 2AUSS 8 Berica, San Bartolo Hospital, Department of Nephrology, Dialysis and Transplantation and International Renal Research Foundation (IRRIV), Vicenza, Italy

**Background and Aims:** Autosomal Dominant Polycystic Kidney Disease (ADPKD) is mainly characterized by renal involvement with progressive bilateral development of renal cysts and volumetric increase of the kidneys, responsible for the progressive loss of renal function that leads to chronic kidney disease (CKD) and the need of renal replacement therapy. There are some cases (doubtful, uncertain) in which it is necessary to perform genetic testing to achieve a definitive diagnosis. It looks like in ADPKD patients, mosaicism could modulate the clinical course of the disease. Mosaicism is characterized by few cell populations with different genomes. In these special cases the diagnosis is very difficult and the genetic analysis could be an important and helpful tool. With this report, we want to highlight the importance of the use of several diagnostic methods in those ‘atypical’ cases where otherwise the analysis would have been negative from a first molecular approach.

**Method:** A 47 years old woman came to our attention with typical picture of ADPKD, arterial hypertension and chronic kidney disease CKD (3b). She had no ADPKD family history, but since she had a son, genetic testing was performed. According to our workflow, first level analysis includes Next Generation Sequencing (NGS). Second level analysis, performed to investigate other genes and large rearrangement, was based on Multiplex Ligation-dependent Probe Amplification (MLPA) analysis of PKD1 and PKD2 genes, using Salsa MLPA ProbeMix P352 PKD1PKD2 kit and ProbeMix P351 PKD1 kit ©MRCHolland. Results: NGS did not detect the presence of any genomic variants. Therefore, second-level genetic analysis (several approaches), showed a large deletion in heterozygosis of the portion comprising the 3-33 exons of PKD1 gene in mosaic in percentage close to the resolution limits of the used technique (25-30%). The same analysis was confirmed in another laboratory.

**Conclusion:** We concluded that the identified large deletion, without establishing the real borders due to MLPA technical restrictions, was present as mosaicism. The variant is not reported, but due to the type of mutation and the clinical picture of the patient, it is to be considered as likely pathogenic. A stepwise genetic approach might be useful in those cases where standard methods do not allow to reach a definitive diagnosis.

**Abstract**

For clinical FD phenotype a 60-year-old woman (index case) with cadaveric donor renal transplantation and unknown cause of renal disease was undergoing genetic investigation. She reported D313Y as single variant in the GLA gene. A prospective analysis of clinical manifestation, genetic and biochemical (lyso-GB3 and enzyme activity) data was performed in all her brothers, sisters and sons. Data were assessed as part of routine follow-up visits.

**Results:** Genotype information of our index case was: nucleotide change c.937G>T, exon 6 involved, amino acid change p.Asp313Tyr, HGMD accession CM930335, mutation type missense. In our cohort comprising n.9 family members: n.5 (55%), n.3 females, n.3 males age range 45-60) had the p.D313Y mutation. In nobody the biomarker lyso-GB3 was elevated. Two brothers (age range of 40-50 y) died for acute cardiovascular attack before genetic investigation was performed. The 5 family members showed the following clinical features: 2 hypertension and cardiac hypertrophy (2M, 44/61y); our index case renal failure, LVH and bruning pains; 2F with burning pains (49/46y). Enzyme replacement therapy (ERT) was started in our index case. Annual routine visits are performed in the others.

**Conclusion:** D313Y mutation seems to correlate with clinically relevant symptoms (mainly cardiovascular and renal) compatible with FD, also without lyso-GB3 elevation. ERT might be considered as therapeutic option not only in patients with already organ involvement, but also in paucisymptomatic to prevent disease progression.

**PATHOGENIC ROLE OF D313Y MUTATION IN FABRY DISEASE**

Rosita Greco, Rosalba Di Vilio, Agata Mollica and Teresa Papalia

Annunziata Hospital, Nephrology Dialysis and Transplantation Department, Cosenza, Italy

**Background and Aims:** Fabry disease (FD) is a multisystem lysosomal storage disorder caused by mutations in the GLA gene. The significance of the mutation p.D313Y in the GLA gene is under debate. Our aim is to evaluated the pathogenic role of the D313Y mutation.

**Method:** For clinical FD phenotype a 60-year-old woman (index case) with cadaveric donor renal transplantation and unknown cause of renal disease was undergoing genetic investigation. She reported D313Y as single variant in the GLA gene. A prospective analysis of clinical manifestation, genetic and biochemical (lyso-GB3 and enzyme activity) data was performed in all her brothers, sisters and sons. Data were assessed as part of routine follow-up visits.

**Results:** Genotype information of our index case was: nucleotide change c.937G>T, exon 6 involved, amino acid change p.Asp313Tyr, HGMD accession CM930335, mutation type missense. In our cohort comprising n.9 family members: n.5 (55%), n.3 females, n.3 males age range 45-60) had the p.D313Y mutation. In nobody the biomarker lyso-GB3 was elevated. Two brothers (age range of 40-50 y) died for acute cardiovascular attack before genetic investigation was performed. The 5 family members showed the following clinical features: 2 hypertension and cardiac hypertrophy (2M, 44/61y); our index case renal failure, LVH and bruning pains; 2F with burning pains (49/46y). Enzyme replacement therapy (ERT) was started in our index case. Annual routine visits are performed in the others.

**Conclusion:** D313Y mutation seems to correlate with clinically relevant symptoms (mainly cardiovascular and renal) compatible with FD, also without lyso-GB3 elevation. ERT might be considered as therapeutic option not only in patients with already organ involvement, but also in paucisymptomatic to prevent disease progression.
A SCREENING AND CLINICAL MANIFESTATIONS OF FABRY DISEASE IN PATIENTS ATTENDING DIALYSIS AND NEPHROLOGY CLINICS IN DURBAN, SOUTH AFRICA

Jillian Singh1, Sherilene Benjamin1 and Alain Assounga2
1Durban University of Technology, Durban, South Africa and 2University of KwaZulu-Natal, Nelson R Mandela School of Medicine, Durban, South Africa

Background and Aims: Fabry disease is inherited in an X-linked manner in which the mutated gene inhibits the functioning of the alpha-Galacosidase-A enzyme causing a deficiency or absence of the enzyme, characterizing it as a progressive, lysosomal storage disorder. Subsequently, the accumulation of globotriaosylceramide (Gb3) in the lysosomes causes damage to tissues and major organs. Fabry nephropathy is one of the major organ complications caused by Fabry disease resulting in end-stage kidney disease. The aim of our study is to determine the prevalence of Fabry disease in our patients.

Method: This study was a prospective, quantitative study. A cohort of 200 male patients with chronic kidney disease (CKD stage 2-5D) was enrolled. A control group of 14 healthy males was also enrolled for this study. The ELISA technique was employed to determine the alpha Gal-A enzyme concentration levels in plasma. A questionnaire using the MSSI scoring system was presented to the participants to identify clinical manifestations. The SPSS Version 27 (IBM, New York, USA) was used to analyse the data.

Results: A cut-off value for the alpha Gal-A enzyme concentration levels of <500 pg/ml was calculated. A total of 17 participants from the patient group (n=11) and the control group (n=6) displayed alpha-Gal-A enzyme levels <500 pg/ml. Using the univariate regression analysis, statistically significant results were revealed between alpha-Gal levels <500 pg/ml and age (P = .007), heat or cold intolerance (P = .049), hypertension (p < .001) and eGFR (p < .001). MSSI scores displayed a negative association (P = .001). The multivariate regression analysis showed that age and MSSI scores retained their significance when eGFR was excluded as a variable, however, with the inclusion of eGFR as a variable, none of the variables retained their significance.

Conclusion: Fabry disease is suspected in 17 participants with alpha-Gal levels of <500 pg/ml. The cause of CKD nephropathy raises interest as conditions such as FSGS have been associated with FD. The low levels of the alpha-Gal enzyme and presentation of the clinical manifestations can be utilized as preliminary findings. Confirmatory tests such as DNA analysis or Gb3 and GL3 analysis are warranted.

ASSOCIATION OF MULTIPLE PLASMA BIOMARKER LEVELS WITH KIDNEY DISEASE ACTIVITY IN FABRY DISEASE

Şeyda Güüz Özcöz1, Zeynep Atli2, Necmi Eren3, Mevlut Tamer Dincer4, Kültügan Turkmen5, Hakon Ozer6, Sinan Trabulsu7 and Nurhan Seyahi8
1Istanbul University-Cerrahpaşa, Cerrahpaşa Medical Faculty, Internal Medicine, Istanbul, Turkey, 2Sinop University, Turkey, 3Kocaeli University, Nephrology, Turkey, 4Istanbul University-Cerrahpaşa, Cerrahpaşa Medical Faculty, Nephrology, Turkey and 8Necmettin Erbakan University, Meram Medical Faculty, Nephrology, Turkey

Background and Aims: Fabry disease is a rare, systemic, genetic, and metabolic lysosomal storage disease. Phenotypic heterogeneity prevents accurate predictions for the disease progression. We aimed to evaluate the association of multiple plasma biomarkers with disease severity in Fabry disease.

Method: In a cross-sectional study, we examined 76 Fabry, 46 CKD patients and 41 healthy controls. We studied KIM-1, MCP-1, YKL-40, TNFR-1, TNFR-2, cystatin-C with enzyme linked immunoassay. Fabry patients on renal replacement therapy were excluded from the analysis.

Results: Demographic, clinical and laboratory data of the study participants are shown in Table 1. eGFR was calculated with creatinine and creatinine-cystatin C using CKD-EPI formula. While there was no difference between Fabry patients and healthy controls regarding eGFR(cr); eGFR(cr-cys) was significantly lower in Fabry patients. Biomarker levels in three groups were shown in Table 2. After performing age, sex and BMI adjusted analysis, MCP-1 was significantly lower in Fabry patients compared to CKD group (p<0.011). MCP-1 was significantly higher in Fabry patients with cardiac involvement than in those without cardiac involvement (p<0.039). KIM-1 was significantly higher in Fabry patients compared to healthy controls (p<0.011). There was no significant difference regarding biomarker levels between Fabry patients with and without kidney involvement. YKL-40 was significantly lower in Fabry patients without kidney involvement compared to both control groups (p<0.025), probably reflecting the effect of ERT.

Conclusion: MCP-1, KIM-1, YKL-40 and Cystatin C seems to be useful markers for the management of Fabry patients. Each biomarker is associated with different aspect of the disease. MCP-1 might be a useful regarding Fabry disease activity especially in patients with cardiac involvement. KIM-1 might be an early sign in Fabry disease. Cystatin-C should be used for...
better management of patients since it shows renal involvement better than creatinine.

FABRY DISEASE: A RARE ENTITY IN THE NEPHROLOGY SETTING
Najjar Mariem1, Rania Dridi1, Hana Ben Braiek2, Hayet Kaaroud3, Fethi Ben Hamida2, Amel Harzallah1 and Ezzedine Abderrahim1
1 Charles Nicolle Hospital, Medecine A Department, Tunisia and 2 Charles Nicolle Hospital, Kidney pathology Laboratory LR005P01, Tunisia

Background and Aims: Fabry disease is a rare genetic disorder that affects multiple organs, including the kidneys. It is characterized by the accumulation of globotriaosylceramide (Gb3) in various tissues and organs, leading to progressive interstitial fibrosis and renal dysfunction. We aim to determine the renal manifestations of Fabry disease in particular the histological aspects.

Method: This study analyzed 9 patients with Fabry disease and renal involvement in a retrospective, single-center analysis. Clinical and biological data, as well as histologic findings, were collected based on patients' observations.

Results: Data was collected from 9 patients, including 7 males and 2 females, with an average age at diagnosis of 25.2 years (ranging from 17 to 32 years). All patients showed depleted activity of alpha 1 lysocidase, confirming the diagnosis. Acrocyrosis and vascular cutaneous lesions (angiokeratomas) were the dominant signs at admission with respectively (n=7; n=4), with only 3 patients being identified through familial screening without symptoms. Uncontrolled Hypertension was noted in 2 patients. Renal manifestations included renal hyperfiltration in 2 cases, isolated proteinuria in 4 patients, and renal failure in 3 others with a mean serum creatinine levels of 240 ± 36 μmol/l. Four patients underwent renal biopsy, which showed characteristic lesions of Fabry disease with sphingolipid accumulation and tubular cell vacuolization. Thickening of the glomerular capillary walls was observed in one patient. Interstitial fibrosis and tubular atrophy were noted in 3 patients. All patients received enzyme replacement therapy. Angiotensin-converting enzyme inhibitors (ACEi) and/or angiotensin II receptor blockers (ARB) were used in 6 patients. Five patients progressed to terminal stage of renal failure requiring dialysis after an average follow-up period of 13±2.7 years. Four patients died from cardiovascular complications.

Conclusion: Early recognition and diagnosis of Fabry disease from the onset of glomerular hyperfiltration and albuminuria are crucial for the initiation of appropriate treatment and management, which can help to delay the progression of renal and other organ damage.

PHARMACOKINETICS OF SETMELANOTIDE IN INDIVIDUALS WITH RENAL IMPAIRMENT: RESULTS FROM A PHASE 1, OPEN-LABEL, SINGLE-DOSE STUDY
Miriam Zacchia1, Andrea Navarria2, Sharon Baughman3, Willem Roux4, Sonali Malhotra5,6,7, Guojun Yuan8 and Metin Cetin6
1 University of Campania Studies ‘Luigi Vanvitelli’, Department of Translational Medical Sciences, Napoli, Italy; 2 Rhythm Pharmaceuticals, Inc., Boston, MA, United States of America; 3 ProPharma Services Corp, Superior, CO, United States of America, 4 Massachusetts General Hospital, Boston, MA, United States of America, 5 Harvard Medical School, Boston, MA, United States of America and 6 Essen University Hospital, Essen, Germany

Background and Aims: Setmelanotide is an approved treatment for chronic weight management and control of hunger in patients aged ≥6 years with specific forms of obesity including Bardet-Biedl syndrome (BBS). Setmelanotide may be considered for patients with renal impairment, including those with BBS, who often experience impaired renal function as a primary feature of the syndrome. This study evaluated the pharmacokinetics (PK) and safety of a single dose of setmelanotide in individuals without BBS who have renal impairment.

Method: This Phase 1, open-label study (NCT04348175) was conducted in 3 centers in the United States. Eligible individuals were aged 18-83 years and had general obesity with a body mass index (BMI) of 24-40 kg/m². Individuals were assigned to a study cohort according to renal function, determined by estimated glomerular filtration rate (normal renal function [healthy volunteers]: ≥90 mL/min/1.73 m²; mild renal impairment: 60-89 mL/min/1.73 m²; moderate renal impairment: 30-59 mL/min/1.73 m²; severe renal impairment: 15-29 mL/min/1.73 m²). A single dose of 2.0 mg of setmelanotide was administered subcutaneously; however, 1.0 or 0.5 mg was administered to most patients with severe renal impairment following safety review of the patient cohorts with mild and moderate renal impairment because of the potential impacts of nausea and vomiting, and consequential dehydration, on renal function. Blood samples were collected for PK analysis from hour 0 up to hour 96 after setmelanotide administration. Patients with renal impairment and healthy volunteers were matched according to sex, age, and BMI. PK parameters in individuals who received <2.0 mg setmelanotide were dose normalized for comparisons across renal function groups. Safety and tolerability were monitored and evaluated.

Results: In total, 32 individuals were included. Age, sex, and BMI were generally similar across cohorts. Setmelanotide PK parameters were comparable regardless of renal function (Table 1). Mean area under the concentration-time curve was higher in individuals with renal impairment compared with healthy volunteers and increased with worsening renal function. Mean clearance was lower in individuals with renal impairment compared with healthy volunteers and decreased with worsening renal function. Thirty individuals (94%) experienced a treatment-emergent adverse event (TEAE), with gastrointestinal disorders (n=22; 69%) having the highest incidence. There were no severe, serious, or fatal TEAEs and no TEAEs leading to withdrawal. There were no meaningful differences in incidence of the most common TEAEs across cohorts.

Conclusion: Minimal differences in PK parameters were observed in individuals with mild and moderate renal impairment compared with healthy volunteers. Findings from this study are consistent with current setmelanotide dosing recommendations, which suggest a modified dosing regimen in patients with severe renal impairment.

#3697
FAMILIAR PAPILLARY RENAL CELL CARCINOMA: A CASE REPORT
Susan McCanellen1, Elhussein Elhassan2, Andrew Green3, Patrick Morrison4, Colm Magee1 and Peter Conlon1
1 Beaumont Hospital, Nephrology, Dublin, Ireland, 2 CHI at Temple Street, Ireland and 3Belfast City Hospital, United Kingdom

Background and Aims: The incidence of Renal Cell Carcinoma (RCC) is the 9th commonest cancer worldwide. It originates from the renal tubular epithelium and to date has been subclassified into five different categories. Of which, papillary carcinoma is one subclassification and it includes two variants: sporadic and hereditary. This case report aims to outline a rare case of hereditary papillary RCC and the implications for the family involved.

Table 1: Setmelanotide Pharmacokinetics Parameters by Renal Function Following a Single Subcutaneous Dose of Setmelanotide.

Abstract
Method: We performed a retrospective assessment of clinical and radiological characteristics of the index patient and affected relatives. Genetic diagnosis and management have been summarised.

Results: A 62-year-old male (II.1) was diagnosed with RCC after presenting with right-sided flank pain and multiple complex cystic lesions within both kidneys. A kidney biopsy revealed a papillary structure with foamy histocytes and clear cell-type epithelium clusters. Immunostaining of tumour cells demonstrated CK7 and P504S positivity consistent with RCC. Subsequently, he underwent bilateral nephrectomies and was rendered anephric, was commenced on haemodialysis. He underwent deceased donor renal transplantation four years later at the age of 66 (HLA 1:2:1, CMV -/-, cRF 35%).

Conclusion: The case outlines a rare form of hereditary RCC and the implications that detection of the genetic variant has meant in terms of early diagnosis of disease. Incidence of RCC is increasing worldwide. Hereditary papillary RCC is rare, it is typically inherited in an autosomal dominant pattern. Germline mutations in the MET proto-oncogene are located at 7q31, which encodes for the tyrosine kinase signaling pathway. Variants lead to uncontrolled activation of MET protein and aberrant cell growth.

Discussion: Hereditary papillary RCC has an estimated incidence of <1:1500000, its rarity highlighted by the fact that only ~35 families have been reported worldwide in literature. In these cases it exhibits 100% penetrance, with patients developing renal cell carcinoma typically between their fifth and sixth decade.

We would like to acknowledge the family involved in this case report. As with many cancers, early diagnosis is helped by detection of a genetic variant, leading to improved long-term disease-free survival. In the case of metastatic papillary RCC 2-year survival is still estimated at 18% (3).

REFERENCES
Background and Aims: Fabry Disease (FD) is a multisystemic disorder that affects the function of major organs, such as the kidneys, the heart, and the central nervous system, reducing the quality of life and leading ultimately to premature death. Early diagnosis and timely treatment are the cornerstones to change the natural history of this disorder.

Method: To evaluate clinical, laboratory and renal histological profiles of FD patients with a classic pathogenic variant (p.G35V), identified by targeted screening in hemodialysis patients followed by family screening, who were under enzyme replacement therapy (ERT), alglucosidase-beta (0.1 mg/kg/e.o.w), for at least 48 months. Kidney biopsy was performed at baseline. Glomerular filtration rate, estimated according to the CKD-Epi equation, 24-h urinary protein and albumin were measured annually. Cardiac manifestations were evaluated by electrocardiogram, transthoracic echocardiography (TTE) or magnetic resonance imaging (cMRI) at baseline and at the end of the study. cMRI was not performed in the index patient, due to CKD 5D, and in a pregnant female patient.

Results: Nine patients (age: 33.8±12.3 years) were followed-up for 80.67±4.43 months. Their main clinical manifestations were hypohidrosis (67%) gastrointestinal symptoms (56%), cornea verticilata and acroparesthesia (100%). In 2 patients (index case and a 46-years old female) entrapment of NO in the abundant stagnant mucus. Were recruited 27 patients with ADPKD and 25 randomly selected controls. We compared nNO measurements between the two groups, stratifying for truncated mutations and eGFR. After stratification according to ADPKD phenotype of the disease is the formation of multiple cysts in the kidneys but in many cases it also involves other organs like heart, brain and lungs. The latters are not yet well studied; some papers report a higher prevalence of bronchiectasis in ADPKD patients compared to the general population; moreover, one work describes the absence of PC-1 in motile cilia of ADPKD pts compared to controls, who actually do express the protein. Based on available literature, we hypothesized that the PC-1 and PC-2 could have a role also in motile cilia. Exhaled nasal nitric oxide (nNO) is an indirect marker of cilia dysfunction, standardized for the screening of primary ciliary dyskinesia, a motile ciliopathy, in which very low levels of nNO are found because of the entrapment of NO in the abundant stagnant mucus.

Method: We recruited 27 patients with ADPKD and 25 randomly selected controls. We compared nNO measurements between the two groups, stratifying for truncated mutations and eGFR. After stratification according to ADPKD genetic mutation, we analyzed separately each of the two subgroups with the control group.

Results: nNO levels were no different in ADPKD patients compared with healthy controls (mean ± standard deviation: 850±240 vs 923±290, \( P = .05 \)), given the entrapment of NO in the abundant stagnant mucus.

Discussion: nNO levels did not differ in ADPKD individuals compared to controls, although lower nNO measurements were observed in ADPKD patients exhibiting a truncated mutation.

Conclusion: Even at the edge of the statistical significance (\( P = .05 \)), given it's confirmed in a wider population, this finding could signify that pts who
carry a more aggressive genotype (PKD-1 truncated mutation) may not express polycystins in motile cilia; this aspect is in line with the verified knowledge that this kind of mutation ends up in the total absence of the protein. On the other hand, pts with a missense mutation may still express the protein in motile cilia, therefore without any functional impairment.

#6931
TWO CASES OF PREGNANCY IN PATIENTS WITH TUBEROUS SCLEROSIS COMPLEX
Tamara Knezevic1, Vanja Ivkovic1,2, Margareta Fistrek Prlic1, Ema Ivandic1, Ivana Yukovic Brinar1,2,3
1University Hospital Centre Zagreb, Division of Nephrology, Hypertension, Dialysis and Transplantation, Zagreb, Croatia, 2University of Rijeka, Faculty of Health Studies, Rijeka, Croatia and 3University of Zagreb, School of Medicine, Zagreb, Croatia

Background and Aims: Tuberous sclerosis complex (TSC) is a rare autosomal dominant genetic disorder that is characterized by formation of benign tumors of the brain, kidney, eyes, heart, lung, liver and skin. The disease is frequently associated with adverse pregnancy outcomes. Our aim is to present two cases of Tuberous sclerosis complex in pregnancy which might be illustrative in the management of these patients.

Method: The first patient was a 32-year-old woman with a history of renal angiomyolipoma (AML) and pulmonic lymphangiomylomatosis (LAM) due to Tuberous sclerosis complex diagnosed at a young age. In the 35th gestational week she had an emergency Cesarean section due to acute retroperitoneal bleeding from angiomyolipoma of the right kidney and gave birth to a preterm male infant (birth mass 2077 g, Apgar 4/6). The patient did not take any medications during the course of pregnancy. Since 2015 she is being treated with everolimus (5 mg/day) due to complications for pulmonic lymphangiomylomatosis, subependymomas and epilepsy and AMLs. After being treated with everolimus (5 mg/day) due to complications for pulmonic lymphangiomylomatosis, subependymomas and epilepsy and AMLs. After the course of the pregnancy she was treated with phenobarbital, folic acid and iron supplementation. Her epilepsy is well-controlled and AMLs show no dynamic in size or number. The second patient was a 29-year-old nulliparous woman who has presented with seizures at the age of 2 and was diagnosed with TSC. At 37th gestational week of a twin pregnancy she gave birth to one male neonate (birth mass 2660 g, Apgar 8/9), while the other fetus died in utero. The neonate (birth mass 2660 g, Apgar 8/9), while the other fetus died in utero. The patient did not take any medications during the course of pregnancy. Since 2015 she is being treated with everolimus (5 mg/day) due to complications for pulmonic lymphangiomylomatosis, subependymomas and epilepsy and AMLs. After being treated with everolimus (5 mg/day) due to complications for pulmonic lymphangiomylomatosis, subependymomas and epilepsy and AMLs. The first patient was a 32-year-old woman with a history of renal angiomyolipoma (AML) and pulmonic lymphangiomylomatosis (LAM) due to Tuberous sclerosis complex diagnosed at a young age. In the 35th gestational week she had an emergency Cesarean section due to acute retroperitoneal bleeding from angiomyolipoma of the right kidney and gave birth to a preterm male infant (birth mass 2077 g, Apgar 4/6). The patient did not take any medications during the course of pregnancy. Since 2015 she is being treated with everolimus (5 mg/day) due to complications for pulmonic lymphangiomylomatosis, subependymomas and epilepsy and AMLs. After being treated with everolimus (5 mg/day) due to complications for pulmonic lymphangiomylomatosis, subependymomas and epilepsy and AMLs.

Results: Conclusion: We have showed two cases with relatively good outcomes which have long-term stable disease. Female patients with TSC have increased risk of hemorrhagic complications of AMLs during pregnancy and it can be complicated by intrauterine growth restriction. A multidisciplinary approach is needed in the planning and monitoring pregnancies in these patients to achieve optimal outcomes.

DIURETIC AND RENOPROTECTIVE EFFECTS OF GOREISAN IN A RAT MODEL OF NEPHROTIC SYNDROME
Satoshi Yamatani, Hideki Fujii, Keiji Kono, Mao Shimizu, Ken Hirabayashi, Kazuo Sakamoto, Kentaro Watanabe, Shunsuke Goto and Shinichi Nishi
Kobe University Graduate School of Medicine, Division of Nephrology and Kidney Center, Kobe, Japan

Background and Aims: Goreisan, a traditional Chinese medicine composed of five herbs, is commonly used for the purpose of control of edema and gastrointestinal symptoms. However, the detailed mechanisms have not been fully elucidated. In clinical settings, nephrotic syndrome often causes edema, mainly due to hypoalbuminemia and sodium retention. Thus, we investigated the effects of Goreisan on the kidney using a rat model of nephrotic syndrome.

Method: A model of nephrotic syndrome was created by a right nephrectomy and subsequent administration of adriamycin using Sprague Dawley rats. Nephrotic rats were randomly divided into three groups at 10 weeks of age as follows: control (control), Goreisan (0.5 g/kg (GL), and Goreisan 1.0 g/kg (GH) groups. Goreisan was administered once a day for 4 weeks. At 14 weeks of age, the rats were sacrificed for the evaluation of blood, urine, mRNA expressions, and kidney histopathology.

Results: Urine volume was significantly increased in the GL and GH groups than in the control group (Δurine volume: control; −1.25±2.48 mL, GL group; 9.83±4.16 mL, GH group; 10.00±2.62 mL). The GH group showed significantly lower urine osmotic pressure compared to the control group. There were no significant differences in urinary sodium excretion and serum arginine-vasopressin levels among the three groups. Subsequently, we assessed the expression of aquaporin (AQP) in kidney tissue using real-time PCR and immunohistochemical staining. The mRNA expression of AQP1, AQP2, AQP3, and AQP4 did not differ among the three groups. However, immunohistochemical staining showed that the localization of AQP2 at the apical plasma membrane of the collecting ducts was decreased by treatment with Goreisan. Furthermore, deterioration of kidney function was prevented by treatment with Goreisan. Histological analysis revealed that glomerular and tubulointerstitial damages were ameliorated in the GL and GH groups compared to the control group (glomerular damage score: control; 2.19±0.05, GL group; 1.71±0.05, GH group; 1.10±0.05, tubulointerstitial damage score: control; 2.55±0.09, GL group; 2.28±0.10, GH group; 2.12±0.10). In addition, urinary 8-OHdG, which is an oxidative stress marker, was significantly lower in the GL and GH groups than in the control group.

Conclusion: Our results suggested that Goreisan may have diuretic and renoprotective effects by suppressing the trafficking of AQP2 to the apical plasma membrane of the collecting ducts and possibly reducing systemic oxidative stress.

EXPLORING THE IMPACT OF POTENTIAL UREMIC TOXINS IN CHRONIC KIDNEY DISEASE BY PROTEOMICS: POTENTIAL BENEFITS OR ADVERSE EFFECTS?
Lovorka Grgurevic1,2, Ivana Vojtušek1, Rudjer Novak1, Grgur Salai1, Stela Hrkač1 and Ivana Yukovic Brinar4
1School of Medicine, University of Zagreb, Department of proteomics, Zagreb, Croatia, 2School of Medicine, University of Zagreb, Department of anatomy and clinical anatomy, Zagreb, Croatia, 3KBC Split, Department of Nephrology and Dialysis, Split, Croatia, 4Clinical Hospital Dubrava, Department of pulmology, Zagreb, Croatia, 5Clinical Hospital Dubrava, Department of Clinical Immunology, Allergology and Rheumatology, Zagreb, Croatia and 6University Hospital Centre Zagreb, 6Department of Nephrology, Arterial Hypertension, Dialysis and Transplantation, Zagreb, Croatia

Background and Aims: Chronic kidney disease (CKD) is a progressive disorder characterized by a gradual reduction in kidney function. Proteomics, a large-scale analysis of protein modifications, has been used to study CKD and identify potential therapeutic targets. Studies have found that CKD is associated with changes in the expression of numerous proteins, including
those involved in inflammation, cell adhesion, and metabolism. Additionally, proteomic studies have been used to identify potentially novel uremic toxins, which are compounds that accumulate in the body due to impaired kidney function.

**Method:** We performed a cross-sectional shotgun-proteomic study of pooled plasma across CKD stages and compared them to healthy controls. After sample pooling and heparin-column purification we analysed proteomes from healthy to CKD stage 1 through 5 participants’ plasma by liquid-chromatography/mass-spectrometry.

**Results:** Our results of proteomic profiling of the plasma of the patients with CKD1-5, including those after kidney transplantation, unequivocally showed that the key processing of the disease, regardless of the type and function of the observed protein groups, occurs in stage 2 of CKD, which we could call the stage - a tipping point. Through the analysis of 453 proteins, 7 established uremic toxins of “middle molecular mass” were identified. Further analysis was conducted to identify potential candidates for new uremic toxins, resulting in the identification of 15 novel proteins that may have a systemic inflammatory effect, atherogenic potential, or increase the risk of cardiovascular diseases.

**Conclusion:** These findings suggest that proteomics can be used to identify novel uremic toxins and provide new insights into the pathophysiology of CKD and selected toxins arrange by toxic, beneficial effect or both. Further research is needed to validate these findings and explore the potential therapeutic implications of targeting these uremic toxins.

**PeroxiRedoxins Are Related to eGFR Decline in IGA Nephropathy, Membranous Nephropathy and Lupus Nephritis: A 5-Year Follow-up**

Natalia Krata¹, Barbara Moszczuk¹, Julia Tanska¹, Marta Monticolo¹, Leszek Paczek¹,², Bartosz Foroncewicz², Krzysztof Mucha¹,²

¹Medical University of Warsaw, Dept. of Immunology, Transplantology and Internal Diseases, Warszawa, Poland and ²Institute of Biochemistry and Biophysics, Polish Academy of Sciences, Warsaw, Poland

**Background and Aims:** Oxidative stress (OS) is known as a disturbance between pro- and antioxidant factors, that may lead to DNA or protein oxidation, resulting in cellular damage. PeroxiRedoxins (PRDXs) are enzymes with an antioxidant properties. They play dominant role in regulation of cellular peroxide levels, which is crucial in maintaining organisms’ oxidative balance. PRDXs types 1-5 are involved in the pathophysiology of various diseases (e.g. cancer, inflammatory, or renal). We aim to study their role as a prognostic marker of eGFR changes in IgA nephropathy (IgAN), lupus nephritis (LN) and membranous nephropathy (MN) patients.

**Method:** This is a retrospective 5-year-follow-up study of 108 IgAN, MN and LN patients, in whom PRDX 1-5 serum levels were assessed with ELISA in 2017. In 2022, we were able to collect the data out of 80 patients: IgAN (n=36); MN (n=22) and LN (n=22). The remaining 28 were considered as lost-to-follow-up, namely: lack of any medical results within last 2 years (n=23); on dialysis (n=2); after renal transplantation (n=2); deceased (n=1). We classified patients depending on the changes of eGFR (decline/stable/increase; Fig. 1) between baseline and after 5 year follow-up and the PRDX levels (high/medium/low; Table 1). The Mann Whitney-U, Kruskal-Wallis and Chi-Square Test were used for statistical analysis, the p-values <0.05 were considered significant.

**Results:** Baseline PRDX measurements indicated, that the mean concentrations of serum PRDX 1-5 differ between the glomerulonephropathies (GN). In 2022, we observed significantly different (P=.012) change of eGFR depending on the GN type. 16/80 individuals had eGFR decline and 75% of them were diagnosed with IgAN. The MN and LN groups had increase of eGFR in the last 5 years in most cases, probably as a result of the treatment. We verified if follow-up eGFR was associated with baseline PRDX levels. The 2022 eGFR differed significantly between the GNs depending on the level of serum PRDX 2, 4 and 5 at baseline (P=.002; P=.009; P=.006, respectively, Table 1).

**Conclusion:** Our results showed the link between serum PRDXs concentration and IgAN, MN and LN follow-up. Importantly, selected PRDXs might be used to predict eGFR decline, particularly in IgAN and LN.

**Tubular Changes in Patients with Autosomal Dominant Polycystic Kidney Disease**

Luca Salomone¹, Silvia Lel¹, Francesca Zippo¹, Francesca Tinii¹, Adolfo Marco Perrotta¹, Silverio Rotondi¹, Lida Tartaglione¹, Marzia Pasquali¹, Rachele Rocca², Mario Mazzei¹ and Sandro Mazzaferré¹

¹Sapienza, University of Rome, Traslation and precision medicine, Rome, Italy and ²Policlínico Umberto I, Italy

**Background and Aims:** Autosomal dominant polycystic kidney disease (ADPKD) is characterized by the presence of multiple cysts, leading to progressive reduction in renal function and systemic involvement. The possible presence of tubular alterations has been suggested, but the mechanisms involved have not yet been fully identified. The study aims to highlight possible tubular alterations in ADPKD patients compared to patients with chronic kidney disease (CKD).
Method: A total of 145 patients were enrolled, including 37 with ADPKD and CKD, while 108 had CKD with the same clinical characteristics, and a comparative analysis of urinary and serum parameters were performed. A venous blood gas analysis was performed on each patient to assess serum pH, lactate concentration, and base excess, and a spot urine test was performed to evaluate urinary pH using a pH meter and specific gravity (SG).

Results: The comparative analysis of serum parameters showed a significant reduction in serum pH (spH) in ADPKD patients (p < 0.001), with a significant increase in lactates (1.3 vs 0.9 mmol/L, p < 0.001) and a significant reduction in base excess (BE) (p < 0.001). The evaluation of urinary parameters in ADPKD patients showed a urinary pH (upH) that was on average more acidic compared to patients with CKD (p < 0.001) with a reduction in the capacity to concentrate urine (p < 0.001). No statistically significant differences were found in terms of glomerular filtration rate between the two groups.

Conclusion: The collected data showed some alterations in the serum and urinary metabolic profile of ADPKD patients compared to the CKD group. The alterations in upH are consistent with those of recent studies in the literature, where it is hypothesized that a urinary concentration defect, already present in early stages, may cause a reduction in upH due to a reduced medullary trapping of ammonium and a reduced presence of bicarbonates. The hypothesis of a preferentially anaerobic metabolism in ADPKD patients is also in line with the increased levels of serum lactates.

Figure 1: Comparative Analysis of urinary parameters in ADPKD patients (n=37) and CKD patients (n=108). (a) Median values of urinary pH. (b) Median values of urinary specific gravity.

Figure 2: Comparative analysis of EGA parameters in ADPKD patients (n=37) and CKD patients (n=108). (A) Median pH values. (B) Median values of HCO₃⁻. (C) Median values of BE. (D) Median lactate values. The circles are the outliers.
Table 1: Comparative analysis between ADPKD patients and CKD patients.

ASYMPTOMATIC NEPHROTIC SYNDROME: AN INTERESTING PRESENTATION OF ADULT ONSET MINIMAL CHANGE DISEASE

Amara Sarwal1, Nirupama Ramkumar1, Patricia Revelo2 and Jo Abraham1

1University of Utah, Division of Nephrology, Salt Lake City, United States of America and 2University of Utah, Division of Pathology, Salt Lake City, United States of America

**Background and Aims:** Minimal change disease (MCD), a predominantly pediatric disease, is less common in adults. Patients often present with florid hypervolemia, manifested by significant lower extremity edema, anasarca, pericardial effusion or pleural effusion. Herein, we present a case of newly diagnosed MCD in an elderly gentleman with an atypical presentation.

**Method:** A 69 year old male with hypertension and benign prostate hypertrophy presented to the emergency department (ED). He was noted to have abnormal labs at an outside clinic on routine testing and was directed to the ED. In the ED, he was found to have a serum creatinine (SCr) of 10.89 mg/dL. Initial urine studies also revealed proteinuria of 11g/g with 6.5 g/g of albuminuria. Other initial labs were significant for a potassium of 4.5 mEq/L, BUN 126 mg/dL and albumin 2.2 g/dL with normal liver enzymes. Renal ultrasound was unremarkable. Upon further discussion with the patient, he endorsed long term daily use of diclofenac for many months. He denied any proton pump inhibitor or recent antibiotic use. He denied any fevers, nights sweats or weight loss to suggest Type B symptoms. There was no personal kidney disease history nor family history of kidney disease. He was a non-alcoholic and non-smoker. We continued to hold further non-steroidal anti-inflammatory medications as well as other nephrotoxic medications. Although patient had elevated SCr and azotemia, he did not meet any acute indications for dialysis and we continued to manage the patient conservatively. Serologies were negative for ANA, ANCA, Anti-GBM, HIV, hepatitis B and C, as well as antiPLA2R. Serum protein electrophoresis, kappa to lambda ratio, complements 3 and 4 were all within normal values. A kidney biopsy was revealing for patchy interstitial inflammatory infiltrate containing mononuclear cells admixed with few eosinophils on light microscopy as well as diffuse foot process effacement on electron microscopy (Figure 2). The patient had a one-week hospital stay with improvement of SCr to 2.29 mg/dL without any prednisone or treatment for MCD. Spot urine protein improved to 7.4 g/g by time of discharge. At clinic follow up 2 weeks later his creatinine had improved to 1.1 mg/dL with UPCR of 0.4 g/g.

**Results:** MCD is a podocytopathy that can occur in up to 10% of adults with nephrotic syndrome [1]. Secondary MCD has been reported with NSAIDs. Steroids are the first line therapy for MCD and can lead to remission in the majority of the cases. In patients who do not respond to steroids, calcineurin inhibitors or mycophenolate can be used. Our patient presented with biopsy proven-MCD that was presumed to be secondary to diclofenac. His clinical presentation was not characteristic of nephrotic syndrome with no edema. Few reports exist of spontaneous remission in these patients with most of the patient requiring steroids. While it is uncommon for patients with MCD to spontaneously resolve, not all patients with NSAID-induced MCD require treatment and these patients could be monitored conservatively.

PROGNOSIS OF CRESCENTIC GLOMERULONEPHRITIS IN ADULTS

Otilia Ciurea1,2, Adela Marasescu1, Nicoleta Petre1,2, Gabriel Mircescu1,2, Cristina-Stela Capusa1,2

1Carol Davila University of Medicine and Pharmacy, București, Romania and 2Nephrology Hospital Dr. Carol Davila, București, Romania

Background and Aims: Crescentic glomerulonephritis (C-GN) is characterized by severe glomerular inflammation and injury that leads to crescent formation, rapid loss of kidney function and severe prognosis in absence of prompt immunosuppressive therapy. Depending on the histological findings, there are three main types of C-GN: anti-glomerular basement membrane antibody GN (anti-GBM GN), immune complex GN, and pauci-immune GN. This study aims to assess whether the kidney and vital outcome are different among the three histologic types of crescentic GN.

Method: This unicentric, retrospective study included seventy-six subjects [50% males, 55 (95%CI 52 to 60) years; eGFR 9.6 (95%CI 7.8-13.7) mL/min and proteinuria 1.9 (95%CI 1.5 to 2.6) g/g] that had undergone a kidney biopsy between 1st January 2008 and 31st December 2017 and had a histologic diagnosis of crescentic glomerulonephritis (crescent formation in more than 50% of the glomeruli). The subjects were followed for a mean of 47.6 (95%CI 33.5 to 61.6) months. Primary endpoints were the need of renal replacement therapy initiation (RRT) and all cause death. Kaplan-Meier method was used to evaluate kidney and patients’ survival and variables related to kidney and vital outcome were evaluated by multivariate Cox proportional hazard modelling. Patients were stratified in three groups according to the type of C-GN: pauci-immune GN (n=58 pts.), anti-GBM GN (n=9 pts.) and immune-complex GN (n=9 pts.).

Results: No demographic differences were found among the three groups. Except for a higher frequency of solid neoplasia in immune-complex GN group (2.7% vs 1.3% in pauci-immune GN vs. 0% in anti-GBM GN; P = .001), no other differences regarding the clinical or laboratory data were identified. Immunosuppressive treatment was very frequent, in more than 80% of subjects, regardless of the group, corticotherapy and cyclophosphamide being the most common immunosuppressive agents. During the follow-up period, 54% of subjects needed RRT and 19.2% died. The frequency of RRT initiation or death was not different among the three groups (P = .9 and P = .4). The univariate time-dependent analysis showed similar survival times among the analysed groups (log rank =0.9) (Figure 1). In the multivariate analysis, the only independent predictor of RRT was lower baseline eGFR (OR 0.49 (95%CI 0.31 to 0.78), P = .03). Time to death did not differ among groups (log rank P = .4) (Figure 2). The only independent predictor of death was higher Charlson comorbidity score (OR 56.8 (95%CI 6.3 to 512), p<0.001) in the Cox analysis.

Conclusion: In this cohort of subjects with crescentic glomerulonephritis, although limited by the low number of subjects, the kidney and vital prognosis seem to be similar indifferent of the histologic type of crescentic glomerulonephritis.
syndromewas positive in 61 cases (41%). The histopathological study showed positive anti-ds-DNA, mean C3 was 29 (84-122 mg/dL), and mean C4 was 0.6 g/24 h. ANA was positive in a diffuse pattern in all cases, ± proteinuria of 2.4 in 28.1%, hypertension in 24.3%, and renal failure in 17.5% with a mean creatinine of 1.75 mg/dL with de novo hematuria, a protein to creatinine ratio (RPC) 1.1 mg/g and candesartan (4 mg twice daily) was started. The patient received the second dose of COVID-19 vaccine 21 days after the first injection. Two weeks later he developed anorexia, nausea and de novo hematuria. He was admitted at the emergency department with deteriorating renal function with a sCr of 5.5 mg/dL, worsening hematuria with dysmorphic red blood cells and proteinuria (RPC 2.9 mg/g). Renal ultrasound was normal. Immunological studies revealed an elevated ANCA-MPO titer of 561. A kidney biopsy was performed and showed a crescentic necrotizing glomerulonephritis. Immunofluorescence confirmed paucimune glomerulonephritis. He was diagnosed with renal limited myeloperoxidase (MPO) ANCA AAV. He started 3 pulses of 500 mg I.V methylprednisolone followed by prednisolone 1 mg/kg/day after that. He also started rituximab (4 doses of 500 mg I.V once week apart). Despite the immunosuppression, the patient never recovered renal function and remained dialysis dependent.

Conclusion: Whether autoimmune diseases can be triggered after vaccination remains a matter of discussion among experts. ANCA associated vasculitis and autoimmune reactions have been reported with COVID-19 infection and following vaccination.

ANCA-ASSOCIATED VASCULITIS FOLLOWING PFIZER-BIONTECH COVID-19 VACCINE: TRUE ASSOCIATION OR CIRCUMSTANTIAL?

Catarina Marouço, Tiago Assis Pereira, Nuno Moreira Fonseca, Maria Do Mar Menezes, Dulce Carvalho, Rita Magriço and Fernando Nolasco
Hospital Curry Cabral, Nephrology Department, Lisbon, Portugal

Background and Aims: Antineutrophil cytoplasmatic antibody (ANCA)- associated vasculitis (AAV) is a small vessel vasculitis hallmarked by the presence of antibodies against antigens in cytoplasmic granules of neutrophils. Vaccines per se stimulate the immune system, including the innate and the adaptive immune response. Therefore, it is possible that an excess of autoimmunity is observed after vaccine administration. Vaccination (notably influenza) is a recognized trigger for the relapse of ANCA-associated vasculitis. ANCA associated vasculitis and autoimmune reactions have been reported with COVID-19 infection and following vaccination.

Results: We report the case of a Caucasian, 62 year-old-man, with a previous history of type 2 diabetes mellitus, hypertension and atrial fibrillation. Blood analysis one year before presentation showed preserved renal function and normal urinalysis. He received the first dose of Pfizer-BioNTech COVID-19 vaccine and two weeks later routine blood analysis showed acute kidney injury with serum Creatinine 1.75 mg/dL with de novo hematuria, a protein to creatinine ratio (RPC) 1.1 mg/g and candesartan (4 mg twice daily) was started. The patient received the second dose of COVID-19 vaccine 21 days after the first injection. Two weeks later he developed anorexia, nausea and de novo hematuria. He was admitted at the emergency department with deteriorating renal function with a sCr of 5.5 mg/dL, worsening hematuria with dysmorphic red blood cells and proteinuria (RPC 2.9 mg/g). Renal ultrasound was normal. Immunological studies revealed an elevated ANCA-MPO titer of 561. A kidney biopsy was performed and showed a crescentic necrotizing glomerulonephritis. Immunofluorescence confirmed paucimmune glomerulonephritis. He was diagnosed with renal limited myeloperoxidase (MPO) ANCA AAV. He started 3 pulses of 500 mg I.V methylprednisolone followed by prednisolone 1 mg/kg/day after that. He also started rituximab (4 doses of 500 mg I.V once week apart). Despite the immunosuppression, the patient never recovered renal function and remained dialysis dependent.

Conclusion: The findings of this study suggest that IFTA is a significant prognostic factor for the progression of renal failure in lupus nephritis, regardless of the class of the disease. The pathogenesis of tubulointerstitial lesions seems to be the result of circulating immune complexes specifically interacting with tubulointerstitial autoantigens.

THE INTERSTITIAL TUBULAR INJURY IN THE COURSE OF LUPUS NEPHRITIS

Najjar Mariem1, Rania Dridi1, Hana Ben Braie1, Hayet Kaaroud1, Fethi Ben Hamida1, Amel Harzallah1 and Ezzeddine Abderrahim1
1Medecine A Department, Tunisia and 2Kidney Pathology Laboratory LR00SP01, Tunisia

Background and Aims: Tubulo-interstitial involvement in lupus nephritis (LN) refers to the presence of interstitial fibrosis and tubular atrophy (IFTA) in the renal biopsies of patients with lupus. The impact of these features on patient outcomes has not been fully established. The aim of this study was to determine the correlation between IFTA and patient outcomes in LN.

Method: A retrospective descriptive study was conducted on 160 patients with systemic lupus erythematosus who underwent renal biopsy between 2020 and 2022. Clinical and biological data, as well as histologic findings, were analyzed to determine the outcomes associated with IFTA in LN. Other causes of tubulointerstitial nephritis like drugs and toxins were excluded.

Results: The study population consisted of 148 females and 12 males, with a mean age of 37.2 years (ranging from 18 to 62 years) at the time of renal biopsy. Hematuria was observed in 62.5% of patients, nephrotic syndrome in 28.1%, hypertension in 24.3%, and renal failure in 17.5% with a mean proteinuria of 2.4±0.6 g/24 h. ANA was positive in a diffuse pattern in all cases, positive anti-ds-DNA, mean C3 was 29 (84-122 mg/dL), and mean C4 was 16.2 (20-40 mg/dL). Other serology - ANCA and P-ANCA were all negative as well as negative HBV and HCV serology. However serology for Sjögren's syndrome was positive in 61 cases (41%). The histopathological study showed mild mononuclear and plasma cell infiltration of the interstitium, and tubular hyaline casts in 87% of cases. Examination of renal vessels was unremarkable in 94.5% of cases. IFTA was present in 72 patients (45%), with the most frequent glomerular involvement being LN class IV (55.5%) followed by LN class III (32.4%) with respectively (P = .09, P = .2) and was associated significantly with the anti-DNA antibody titer (P = .003). The severity of these lesions was found to be independently correlated with worsening of renal failure at 6 months follow-up (P = .02).

Conclusion: The findings of this study suggest that IFTA is a significant prognostic factor for the progression of renal failure in lupus nephritis, regardless of the class of the disease. The pathogenesis of tubulointerstitial lesions seems to be the result of circulating immune complexes specifically interacting with tubulointerstitial autoantigens.

ANCA-ASSOCIATED VASCULITIS FOLLOWING PFIZER-BIONTECH COVID-19 VACCINE: TRUE ASSOCIATION OR CIRCUMSTANTIAL?

Catarina Marouço, Tiago Assis Pereira, Nuno Moreira Fonseca, Maria Do Mar Menezes, Dulce Carvalho, Rita Magriço and Fernando Nolasco
Hospital Curry Cabral, Nephrology Department, Lisbon, Portugal

Background and Aims: Antineutrophil cytoplasmatic antibody (ANCA)- associated vasculitis (AAV) is a small vessel vasculitis hallmarked by the presence of antibodies against antigens in cytoplasmic granules of neutrophils. Vaccines per se stimulate the immune system, including the innate and the adaptive immune response. Therefore, it is possible that an excess of autoimmunity is observed after vaccine administration. Vaccination (notably influenza) is a recognized trigger for the relapse of ANCA-associated vasculitis. ANCA associated vasculitis and autoimmune reactions have been reported with COVID-19 infection and following vaccination.

Results: We report the case of a Caucasian, 62 year-old-man, with a previous history of type 2 diabetes mellitus, hypertension and atrial fibrillation. Blood analysis one year before presentation showed preserved renal function and normal urinalysis. He received the first dose of Pfizer-BioNTech COVID-19 vaccine and two weeks later routine blood analysis showed acute kidney injury with serum Creatinine 1.75 mg/dL with de novo hematuria, a protein to creatinine ratio (RPC) 1.1 mg/g and candesartan (4 mg twice daily) was started. The patient received the second dose of COVID-19 vaccine 21 days after the first injection. Two weeks later he developed anorexia, nausea and de novo hematuria. He was admitted at the emergency department with deteriorating renal function with a sCr of 5.5 mg/dL, worsening hematuria with dysmorphic red blood cells and proteinuria (RPC 2.9 mg/g). Renal ultrasound was normal. Immunological studies revealed an elevated ANCA-MPO titer of 561. A kidney biopsy was performed and showed a crescentic necrotizing glomerulonephritis. Immunofluorescence confirmed paucimmune glomerulonephritis. He was diagnosed with renal limited myeloperoxidase (MPO) ANCA AAV. He started 3 pulses of 500 mg I.V methylprednisolone followed by prednisolone 1 mg/kg/day after that. He also started rituximab (4 doses of 500 mg I.V once week apart). Despite the immunosuppression, the patient never recovered renal function and remained dialysis dependent.

Conclusion: Whether autoimmune diseases can be triggered after vaccination remains a matter of discussion among experts. ANCA associated vasculitis and autoimmune reactions have been reported with COVID-19 infection and following vaccination, which prompts the question whether this response could be a direct reaction to the RNA present in the vaccine. While an association with de novo ANCA vasculitis and COVID-19 vaccine may be possible, further investigation is necessary.

RENA L LIMITED VASCULITIS: DATA FROM A CROATION REFERR AL CENTER

Matija Crnogorac1, Patricia Kacinar1, Luka Torić1, Dino Kasumović1, Ana Živk1, Miroslav Tišlar2, Danica Galešić Ljubanović3, Kresimir Galesić1 and Ivica Horvatić1
1Dubrava Clinical Hospital, Department of Nephrology and Dialysis, Zagreb, Croatia, 2Galway University Hospital, Department of Internal Medicine, Galway, Ireland and 3Dubrava Clinical Hospital, Department of Clinical Pathology, Zagreb, Croatia

Background and Aims: Small vessel vasculitis and in particular ANCA associated vasculitis (AAV) are diseases with variable clinical presentation. Renal limited vasculitis (RLV) can vary in presentation and characteristics compared to systemic disease. There is a tendency to categorise RLV as a part of microscopic polyangiitis (MPA) spectrum though there seem to be differences in terms of both histology and serology between RLV and MPA. We present data on patients with renal limited vasculitis from our referral center.
Method: This study included 106 consecutive AAV patients with biopsy proven renal involvement in the period from 2007-2017. Category variables were analysed with Fisher Exact testom and continuous with Kruskal-Wallis testom. Statistical difference was then analysed posthoc with Chi-square test. Kaplan Meyer survival analysis and multivariate Cox proportional hazard regression analysis were used to explore difference between clinical phenotypes and finding significant predictors regarding outcomes which were defined as combined outcome end-stage renal disease and death (ESRD), ESRD alone, the death alone and relapse rate.

Results: Out of 106 AAV patients with renal involvement in our database: 66 (61.1%) MPA, 20 (18.5%) GPA (granulomatosis with polyangitis), 20 (18.5%) RLV. In RLV group 14 (70%) were female and average age was 55 (IQR 47-60). Average Scr in RLV group was 234 μmol/l (IQR 168-376,5) and median proteinuria was 3.3g/24h (IQR 0,9-3,8) and most of these patients were treated with either nephrotic syndrome (30%) or RPGN (30%). Serologically 90% of RLV patients were ANCA negative and 10% were MPO-ANCA positive. Histologically (Berden classification) 60% had mixed class, 25% crescentic, 10% focal and 1% sclerotic. Average BVAS score was 14 (IQR 12-17). Compared to MPA and GPA, RLV patients were younger (p=0,058), had less expressed constitutional symptoms (p=0,013) with lower average BVAS (p=0,0001) and lower CRP levels (p=0,001). Though there was no significant difference of average Scr level RLV patients presented more often with nephrotic syndrome (p=0,014), had histological predominantly mixed class (p=0,006) and higher interstitial fibrosis and tubular atrophy (IFTA) percentage (p=0,086). Interestingly, compared to MPA and GPA majority of RLV patients were ANCA negative (p=0,001). There were no statistically significant differences in treatment used both in induction (including need for dialysis and/or PLEX) or remission maintenance treatment between RLV, MPA and GPA group. In survival analysis there was no statistical differences for all of the outcomes between RLV group, MPA and GPA group.

Conclusion: RLV can be challenging disease considering its clinical presentation but also characteristics of renal involvement in terms of more often nephrotic proteinuria and higher IFTA percentage. This might suggest that these patients could have slower disease course (so called slower progressors). Also interestingly in our cohort most of these patients were ANCA negative which also makes diagnosis predominantly a combination of clinical presentation and histology thus prompting a question of how should we classify RLV within a spectrum of small vessel vasculitis. More research is needed to better understand the RLV.

KLOTHO DEFICIENCY INDUCES REGULATORY T CELLS IN MURINE LUPUS NEPHRITIS
Tsuneo Takenaka1, Yoshifumi Kurosaki2, Naohito Inoue3, Akira Nishiyama4 and Matsuhiko Hayashi5
1International University of Health and Welfare, Nephrology, Tokyo, Japan, 2Kitsato University, Biochemistry, Kanagawa, Japan, 3Saitama Medical University, Nephrology, Saitama, Japan, 4Kagawa University, Pharmacology, Kagawa, Japan and 5Keio University, Nephrology, Tokyo, Japan

Background and Aims: Recent studies demonstrate that klotho deficiency participate in various chronic kidney disease. However, it has not been fully assessed the influence of klotho in autoimmune kidney diseases. On the one hand, klotho is known but rare entity, where calcineurin inhibitor treatment may be required to generate and maintain regulatory T cells with inducing FOXP3, an important cell population for immunological tolerance.

Method: NZBW1F mice were used as a model of lupus nephritis. NZBW1F mice were housed separately in metabolic cage, and divided into two groups (n=10 for each): one group was treated with daily subcutaneous injection of klotho protein (20 μg/kg/day), and the other received vehicle alone. Systolic blood pressure was measured by tail-cuff method. Glomerular filtration rate was assessed using FITC-inulin. Four weeks later, the animals were killed to harvest the spleen and kidneys for analyses.

Results: Klotho supplementation suppressed blood pressure, 8-epi-prostaglandin F2α excretion and renal angiotensin II levels (p<0.05 for all) without changes in albuminuria and glomerular filtration rate in NZBW1F mice. Exogenous klotho protein supplementation increased serum klotho levels, urine klotho excretion, and endogenous renal expression of klotho in NZBW1F mice (p<0.05 for all). Surprisingly, anti-double strand DNA antibody was slightly elevated in klotho-treated NZBW1F mice (p<0.05). Glomerular pathology and interstitial cell infiltration were similar between 2 groups. The spleen tended to be greater in klotho-treated group, but statistical significance was not observed. In concisely, CD4+FOXP3+ T cells were unaltered between 2 groups. However, klotho supplementation reduced CD4+FOXP3+ T cells in spleen of NZBW1F mice (p<0.05).

Conclusion: The present data indicated that klotho protein supplementation suppressed blood pressure, 8-epi-prostaglandin F2α excretion and renal angiotensin system, ameliorating blood pressure and oxidative stress. Our results suggest that klotho supplementation worsened auto-antibody, possibly by inhibiting TGFβ with resultant deterioration in regulatory T cells. The present findings implicate that although klotho may not be suitable for the management of autoimmune kidney diseases, such as lupus and ANCA-related nephritis, klotho supplementation for dialysis patients could mitigate against the defect in cellular immunity and susceptibility to infections including tuberculosis and COVID-19.

NEPHROTIC SYNDROME IN LIVER DISEASES: PRESENTATION OF TWO UNUSUAL AND INSTRUCTIVE CASES
Nóra Lédi1, Deján Dobizi2 and Anikó Folhofer3
1Semmelweis University, Department of Internal Medicine and Oncology, Budapest, Hungary and 2Semmelweis University, Department of Pathology, Forensic and Insurance Medicine, Budapest, Hungary

Background and Aims: However, there are known associations between chronic liver diseases and glomerulopathies, here we report two rare cases, where diagnostic and therapeutic challenges influenced the patients’ care.

Method: The patients’ medical parameters were obtained from the electronical charts of the hospital. Kidney biopsy samples were examined with immunofluorescence (frozen samples), light microscopy (paraffin embedded tissue, 2-3 μm sections) and electron microscopy (1 μm, toluidine blue). The follow-up time was 24 months for case 1 and 23 months for case 2. Both patients gave written consent to the presentation of the reports.

Results: Case 1: A 42-year-old man with recent pulmonary embolism was presented in our hospital with nephrotic syndrome and reduced kidney function (estimated glomerular filtration rate (eGFR): 43 ml/min/1.73 m², urinary protein/creatinine ratio (UPCR): 2124 mg/mmol, serum albumin: 24 g/L). Kidney biopsy confirmed primary membranous nephropathy (MN). The anti-phospholipase-A-2 receptor (aPLA2R) was positive in high titer, and PLA2R positivity was also seen in the renal sample. Additionally, an active hepatitis C (HCV) infection with viremia was confirmed. The nephrotic syndrome was worsened with severe edema requiring ultrafiltration; therefore, after one-week direct anti-HCV therapy, mephyblendesilone was started. Immunosuppressive therapy had to be determined soon due to severe infections. With combined direct antiviral treatment, HCV PCR test became negative, which was followed by the disappearance of the aPLA2R antibodies. The patient’s kidney function stabilized and there are no symptoms of nephrotic syndrome (eGFR: 52 ml/min/1.73 m², serum albumin: 37 g/L, UPCR: 321 mg/mmol).

Case 2: A 66-year-old woman was admitted to the hospital with coronavirus disease (COVID)- associated pneumonia. At admission, nephrotic syndrome was diagnosed (eGFR: 29 ml/min/1.73 m², serum albumin: 22 g/L, proteinuria: 8 g/day). Additionally, elevated gamma glutamyl transferase was registered. Immune serology was negative for aPLA2R, but antinuclear antibodies (anti-cytoplasm, chromatin, Ro), and anti-mitochondrial antibodies (AMA-M2) were positive. Biopsies were performed after the COVID infection. Liver biopsy confirmed primary biliary cholangitis (stage 1-2), while the kidney biopsy showed secondary membranous nephropathy with signs of potential monoclonal gammopathy (monoclonal immunoglobulin-G1-kappa deposits). After the exclusion of malignancies, monoclonal gammopathy, and other causes of the secondary MN, PBC-associated MN was diagnosed. Based on case reports in the literature, cyclosporine A treatment was started. The patient reached complete remission in 5 months (no significant proteinuria, stable eGFR around 34 ml/min/1.73 m²).

Conclusion: The association of an active HCV infection and an aPLA2R positive MN has not been reported in the literature. Nephrotic syndrome and the aPLA2R positivity disappeared related to the direct antiviral treatment, which may indicate a diagnosis of secondary MN. PBC-associated secondary MN is a known but rare entity, where calcineurin inhibitor treatment may reduce the symptoms of nephrotic syndrome.

**POST-COVID-19 ANTI-GLOMERULAR BASEMENT MEMBRANE DISEASE: TWO CLINICAL CASES**

Carolina Branco, Joana Gameiro, João Oliveira, Bernardo Marques Da Silva, Nadiesda Peres, José Agapito Fonseca, Paulo Fernandes, Iolanda Godinho, Cristina Outerelo, Sofia Jorge, José António Lopes and Estela Nogueira

Centro Hospitalar Universitário Lisboa Norte, Nephrology and Renal Transplantation, Lisboa, Portugal

**Background and Aims:** Acute kidney injury is a common complication in patients hospitalized with COVID-19, has multiple aetiologies, and is usually multifactorial. We present two cases of anti-glomerular basement membrane (anti-GBM) disease diagnosed after SARS-CoV-2 infection, suggesting a causal correlation.

**Case Reports:** A 76-year-old female, with chronic kidney disease (serum creatinine 1.5mg/dL), hypertension, weight loss (16 Kg/6 months) and a pancreatic nodule under surveillance, presented to the emergency department with 1 week of nausea, vomits, diarrhoea and oliguria, as well as a history of mild SARS-CoV-2 infection 2 weeks before presentation. Lab work revealed severe anaemia (7.4 g/dL), inflammatory markers elevation, nephrotic proteinuria (proteinuria/creatininuria ratio 30 g/g), leucoerythrocyturia, serum creatinine of 19.3 mg/dL, hyperkalaemia and metabolic acidosis requiring dialysis induction. Renal ultrasound showed signs of chronicity and several cysts. Aetiological study disclosed positive anti-GBM antibody (1800 U/L) and negative ANCA. Complementary study failed to identify pulmonary involvement or neoplasms. Given the severity of the renal dysfunction along with the absence of alveolar haemorrhage, immunosuppression and plasmapheresis were not initiated. Patient was discharged and remains dialysis dependent.

A 65-year-old male smoker with type 2 diabetes and hypertension, weight loss (16 Kg/6 months) and a history of dyspnoea and haemoptysis in the past 3 days. Lab work exposed moderate anaemia (9.7 g/dL), elevated inflammatory markers, serum creatinine of 1.18 mg/dL (previously 0.8 mg/dL), leucoerythrocyturia and positive SARS-CoV-2 test. Angio-Computed Tomography exhibited known pulmonary fibrosis and possible bacterial superinfection. Despite antibiotic therapy (10 days of levofloxacin), haemoptysis remained and kidney function continuously worsened (serum creatinine 2.1 mg/dL). Complementary study showed positive ANCA-MPO (1125.4 U/L) and anti-GBM antibody (460.8U/L). Renal ultrasound was innocent. Kidney biopsy revealed: 6 glomeruli with cellular crescents with segmental necrosis, 3 with focal Bowman's capsule rupture; erythrocyte casts; intimal arterial fibrosis; moderate tubular atrophy; diffuse linear deposits of IgG. Immunosuppression was initiated with prednisolone (1 mg/Kg/day), cyclophosphamide (3x 12.5mg/Kg;750 mg, 2x 500 mg), rituximab (2x 1g), immunoglobulin (1x 2 g/Kg) and plasmapheresis (15 sessions). Kidney function continued to deteriorate (maximum serum urea 306 mg/dL, maximum serum creatinine 6.92 mg/dL) requiring dialysis induction 3 weeks after the beginning of immunosuppression. Even though haemoptysis ceased, the patient remains dialysis dependent 8 months after.

**Conclusion:** Literature reports an increase of Anti-GBM disease since the beginning of the pandemic. The presented cases support the apparent correlation, suggesting SARS-CoV-2 as a precipitant of this disease by endothelial injury with basal membrane exposure and autoantibody development. In the second case, the authors assume a subacute ANCA-MPO vasculitis with superimposed anti-GBM (eventually precipitated by COVID-19). Even though the causal association is not established, we highlight the importance of clinical suspicion of this rare aetiology in cases of acute kidney injury after SARS-CoV-2 infection.

**ASSOCIATION OF URINE PROTEIN EXCRETION LEVELS, AS A MEASURE OF DISEASE ACTIVITY, AND QUALITY OF LIFE IN IGA NEPHROPATHY PATIENTS**

Jonathan Barratt1, Sarah Clayton2, Mollie Lowe1, James Jackson2, Adam Roughley3 and Wan Tsong3

1 University of Leicester, Department of Cardiovascular Sciences, Leicester, United Kingdom, 2 Adelphi Real World, Bollington, United Kingdom and 3 Omeros Corporation, Health Economics & Outcomes Research (Medical Affairs), Seattle, United States of America

**Background and Aims:** Little is known about the quality of life (QoL) of patients with IgA nephropathy (IgAN). Understanding the relationship between disease activity (as measured by urine protein excretion [UPE]) and QoL could allow decision-makers to understand how treatments that improve UPE might improve patient QoL.

**Methods:** The 2021 United States subset of the Adelphi IgAN Disease Specific Programme™ was a point-in-time survey of 43 nephrologists (who completed structured forms for 305 IgAN patients) and 70 patients (who elected to complete patient surveys of the 305). This analysis utilised physician-reported data (patient demographics, disease characteristics, and current 24-hour UPE levels [categories: <0.5, >0.5 to ≤1, >1 to ≤2, >2 to ≤3.5, >3.5 grams/day]) and patient-reported data (symptoms, Kidney Disease Quality of Life [KDQOL] scores, and EQ-5D scores). The association between UPE and patient-reported symptoms was evaluated using chi-squared and Fisher’s exact tests. The association between UPE and QoL (KDQOL, EQ-5D) was evaluated using generalized linear regression to adjust for age, sex, chronic kidney disease stage, corticosteroid use, and non-steroidal immunosuppressant use.

**Results:** The analytical dataset included 69 patients with UPE data (reported by 8 physicians) out of the 70 patients who completed the patient survey. Of these 69, data were complete for the symptoms (n=63), KDQOL (n=60), and EQ-5D (n=67). Patients were an average age of 43 years, an average BMI of 26.3, 49% male, 55% White, 23% Asian, 64% never smokers, 78% in full-time occupation, and 74% with commercial health insurance. The most prevalent comorbidities were hypertension (33%), hyperlipidaemia (30%), and diabetes (11%). UPE was not associated with any demographic characteristics, regular dialysis, or kidney transplants. Among comorbidities, higher UPE was associated with a higher percentage of hyperlipidaemia (P = .03). Among medications for IgAN, higher UPE was associated with a higher percent use of diuretics (P = .046), sodium-glucose co-transporter 2 inhibitors (P = .002), corticosteroids (P = .0009), non-steroidal immunosuppressants (P<.0001), and anti-depressants.

**Conclusion:** Increased UPE is associated with worse QoL in IgAN. Further studies are needed to determine the most effective treatments to improve UPE and QoL in IgAN patients.

**Abstract**

Background and Aims: Crescentic glomerulonephritis (CrGN) is a disease presented as nephritic syndrome with hypocomplementemia usually secondary to a skin or throat infection by beta hemolytic Streptococcus and with histopathological findings of endocapillary proliferation. C3 deposits along the capillary wall and mesangium, subepithelial immune complex deposits and IF positive for IgG. There are other unusual presentations of PIGN with IgA dominance or C3-IgA codominance.

Method: A 58-year-old Guatemalan male, with history of one-week duration pain in the right upper quadrant associated with jaundice, diagnosed with cholangitis and intravenous antibiotics use. History of consumption of 10 beers a month for 40 years. No other medical history. During hospitalization, presented a lower-limb cellulitis, for which clindamycin was started. Blood cultures were taken and were positive for S. epidermidis and AKI (Cr 2.84 mg/dl) was observed, associated with de novo appearance of hematuria (80% acanthocytes), proteinuria (580mg/day) and hypertension. Diagnostic approach for nephritic syndrome was performed obtaining: C3 0.592 (low) ANA, ANCA, HIV-HCV-HBV negative, total cholesterol 184 mg/dl, albumin 2.78 g/dl.

Results: Renal biopsy was performed and reported: PIGN with IgA dominance with extra capillary proliferation. Reason why pulses of methylprednisolone were given for 3 days and then oral prednisone (1 mg/kg/day), progressively decreasing it until it was discontinued. Resolved the soft tissue infection and was discharged. At 1-month follow-up as outpatient, was evidence of a 50% decrease in proteinuria compared to baseline, disappearance of hematuria but with persistent of high Cr (2.09 mg/dl).

Conclusion: IgA-dominant PIGN is characterized by usually presenting in patients >60 years with DM, alcohol consumption and staphylococcal skin infections. It can present hypocomplementemia and histopathological findings are characterized by IgA dominance over C3 and no IgG in IF. Elevated serum IgA levels may be involved in the pathogenesis. Treatment is based on eradication of the infection with antibiotics and in some cases the use of steroids is suggested depending on the aggressiveness of the lesion and the presence of crescents in the renal biopsy. It has worse prognosis than the traditional PIGN.

**CRESCENTIC GLOMERULONEPHRITIS IN A PAEDIATRIC POPULATION: A SINGLE-CENTRE EXPERIENCE FROM SOUTH ASIA**

Basavaraj Sajjan¹, Dharmandr Bhadouria¹, Narayan Prasad¹, Anupama Kaul¹ and Manoj Jain²

¹Sanjay Gandhi Postgraduate Institute of Medical Sciences, Nephrology, Lucknow, India and ²Sanjay Gandhi Postgraduate Institute of Medical Sciences, Pathology, Lucknow, India

**Background and Aims:** Crescentic glomerulonephritis (CrGN) is defined clinically by Rapidly progressive renal failure due to crescent formation in ≥ 50% of glomeruli. Most of these patients have a relatively poor prognosis. Therefore, early diagnosis and treatment of these patients may help to prevent renal complications. There is a scarce data on pediatric CrGN. We aim to study the etiopathogenesis and outcome of CrGN in children and adolescents.

**Method:** Retrospective observational study of pediatric patients of age ≤ 18 years with biopsy-proven CrGN from January 2010 to December 2021. Clinical and laboratory data with validated renal biopsy report were obtained from the hospital information system. CrGN was defined as crescents in ≥ 50% glomeruli. Rapidly Progressive Glomerulonephritis (RPGN) is the clinical presentation of CrGN, which is classified based on immunofluorescence findings and serology. Risk factors predicting poor renal outcome were determined.

**Results:** Of 47 patients (13.8% of total biopsy proven CrGN) patients, 30 were male patients (M:F ratio 1.7:1) and median age of 14 (range 7–18) years. 32 (68%) were ANCAnegative (71%). Poor renal outcome is related to severity of initial presentation and extent of IFTA, and serum creatinine at presentation.

**Conclusion:** Immune complex GN is the most common etiology, that constitutes 68% of patients with crescentic GN. Majority of pauci-immune GN were ANCA negative (71%). Poor renal outcome is related to severity of initial presentation and extent of IFTA.

Arunkumar Subbiah¹ and Sudarshan K²

¹AIIMS, New Delhi, Nephrology, New Delhi, India and ²JIPMER, Pediatrics, Puducherry, India

**Background and Aims:** Lupus nephritis is an important risk factor for morbidity and mortality in systemic lupus erythematosus. During the past three decades, extensive research has been done to address this important complication and devise better management strategies. In this article we aimed to perform a thorough assessment of the research productivity in lupus nephritis by identifying the 100 most-cited articles in lupus nephritis.

**Methods:** The top 100 most-cited English language articles on lupus nephritis from 1990 were examined by bibliometric analysis from the Google Scholar

ANCA AND IGA NEPHROPATHY: ASSOCIATION OR PROGNOSTIC FACTOR

Nouha Ben Mahmud, Meriem Ben Salem, Manel Ben Salah, Ahmed Letaief, Mouna Hammouda, Aloui Sabra and Habib Skhiri

Monastir, Tunisia

Background and Aims: Immunoglobulin A (IgA) nephropathy (IgAN), the most prevalent form of primary glomerulonephritis worldwide, is characterized by mesangial cell proliferation, matrix expansion, and mainly mesangial IgA deposition, often in conjunction with C3 and IgG and/or IgM. Its pathogenesis is enigmatic. It is reported that approximately 35-42% of IgAN patients have a history of macrohaematuria before kidney biopsy. Its a benign pathology which sometimes could be associated with crescentic proliferation and more rarely by the presence of ANCA antibodies.

Method: We retrospectively analyzed the epidemiologic, clinical and histological data of 27 patients with IgA nephropathy proven by biopsy and we compared 2 groups ANCA positive and ANCA negative patients.

Results: The present study involved 27 patients, 18 men and 9 women, the average age was 27.9 years 3 patients were ANCA positive compared to 24 ANCA negative; (2 were MPO-ANCA and 1 PR3-ANCA). ANCA positive patients were older, with more severe initial renal function, lower hemoglobin, and a higher percentage of general symptoms than the ANCA negative ones. Patients were older, with more severe initial renal function, lower hemoglobin, and a higher percentage of general symptoms than the ANCA negative ones. ANCA positive patients with IgA nephropathy had a higher percentage of crescentic glomeruli (54.5%) compared with ANCA-negative patients with crescentic IgA nephropathy (26%). The ANCA positive patients were all treated by solumedrol bolus and oral corticosteroid and showed more severe prognosis, the 3 patients progressed to ESKD. 4 ANCA-negative patients were treated with oral corticosteroid, some from the other 20 patients have been put on renin angiotensin system blockers treatment and thy showed a better renal prognosis.

Conclusion: ANCA patients with ANCA positivity showed more severe clinical and histological features when compared with ANCA-negative IgAN patients and lower renal prognosis. The ANCA antibodies should be screened in patients with severe forms of IgAN.

A CASE OF PODOCYTE DISEASE WITH AZOTEMIA FOLLOWING TREATMENT WITH INTRAVENOUS IBANDRONATE
Beom Kim1, Yerin Chung1, Woojin Jang1, Jin Seon Jeong1, Sanghee Lee1, Dong-Young Lee1, Kyounghyoub Moon1 and Huiseo Kim2

1Veterans Health Service Medical Center, Division of Nephrology, Department of Internal Medicine, Seoul, Rep. of South Korea and 2Gwangmyeong Sungae Hospital, Department of Nephrology, Gwangmyeong, Gyeonggi-do, Rep.of South Korea

Background and Aims: Bisphosphonate use may induce several types of nephrotoxicity. There are many reports on pamidronate-associated glomerular disease, such as focal segmental glomerulosclerosis and zoledronate-associated acute tubular necrosis. However, there are limited reports on ibandronate-associated nephrotoxicity. Herein, we describe a case of podocyte disease accompanied with azotemia following intravenous administration of ibandronate.

Method: Case report

Results: An 88-year-old female was referred to the emergency room due to grade 4 edema that developed 1 month before. The patient was diagnosed with osteoporosis 20 months earlier, for which she received quarterly intravenous administration of ibandronate (3 mg). The last dose was administered 2 weeks ago. The patient had no history of diabetes, hypertension, or chronic kidney disease. Laboratory tests revealed heavy proteinuria with a protein/creatinine ratio (PCR) of 32 and hypoalbuminemia (1.9 g/dL) with elevated serum creatinine (sCr) (1.8 mg/dL). Values of serum complement and electrophoresis were within normal ranges. The renal ultrasonogram was unremarkable. A renal biopsy was performed and light microscopy showed mild mesangial hypercellularity and segmental amorphous collagenous deposition in the glomerulus (Fig. 1-A). The tubules revealed focal marked atrophy and interstitial fibrosis (Fig. 1-B). Immunofluorescence studies were unremarkable. Electron microscopy showed diffuse effacement of foot processes and no electron-dense deposit (Fig. 1-C), consistent with podocyte disease favoring focal segmental glomerulosclerosis. The patient was treated with tacrolimus and fimasartan. Steroid use was spared owing to severe osteoporosis. Three months later, the edema subsided and laboratory findings improved (PCR 0.64, serum albumin 4 g/dL, sCr 1.23 mg/dL).

Conclusion: Compared to pamidronate and zoledronate, ibandronate is more highly protein-bound with a significantly shorter renal tissue half life, which might explain the rarity of ibandronate-related nephrotoxicity. Contrary to the trend of other bisphosphonates nephropathies, our case showed simultaneous podocyte disease and tubule damage. We recommend close monitoring of proteinuria and renal function for prompt nephrotoxicity detection in patients treated with ibandronate.
Figure 1: Renal Biopsy was consistent with podocyte disease favoring as focal segmental glomerulosclerosis. A. The light microscopy (Periodic acid-Schiff staining, X 400). showed normal size of glomerulus, mild mesangial hyper-cellularity and segmental amorphous collagenous deposition in glomerulus. B. Tubules revealed focal marked atrophy, interstitial fibrosis. C. Electron microscopy showed diffuse effacement of foot processes and no electron-dense deposit.

#4773
INFECTIVE ENDOCARDITIS COMPLICATED BY RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS: BEYOND ANTIBIOTICS - TO TREAT OR NOT TO TREAT?
Carla Nicolau, Miguel Bigotte Vieira, Maria Do Mar Menezes, Mário Góis, Helena Viana, João Sousa and Manuel Anibal A. Ferreira
Hospital Curry Cabral, Nephrology, Lisboa, Portugal

Background: A significant proportion of patients with infective endocarditis, present with acute renal failure related to infective endocarditis-associated glomerulonephritis (IEAGN). However, IEAGN differs from other infection-related glomerulonephritis because it may present with clinical and serological disturbances resembling autoimmune diseases such as antinutrophil cytoplasmic antibody (ANCA)-associated vasculitis. Its development introduces the dilemma of determining the best treatment approach. Immunosuppressive therapy added to antibiotic treatment may be beneficial for recovery of renal function in some cases of IEAGN with positive ANCA serology, although this approach is still controversial.

Case presentation: A 32-year-old man presented with fever, fatigue, purpura and rapidly progressive glomerulonephritis. He had a history of atrioventricular septal defect corrected at 9 years of age. Blood analysis showed anemia, acute kidney injury and positive ANCA proteinase 3 (PR3). Urine analysis revealed hematuria and proteinuria. Echocardiogram showed vegetation on the mitral valve with moderate to severe mitral regurgitation. Blood cultures showed Streptococcus mitis. After 14 days of intensive antibiotic regimen, kidney function rapidly deteriorated and ANCAtiters remained high. Arenal biopsy was performed and showed crescentic necrotizing glomerulonephritis with deposition of C3 and IgM – compatible with infection-related glomerulonephritis. Treatment was initiated with pulses of methylprednisolone, low dose of corticosteroids and intravenous immunoglobulin, combined with antibiotics. Renal function dramatically improved in less than a week. At three months of follow-up, kidney function remains stable and ANCA serology negative.

Conclusion: In infective endocarditis, ANCA antibodies might have an important pathogenic role rather than secondary phenomena. We suggest that patients with IEAGN, that despite adequate antibiotic regimen present, present with kidney deterioration and evidence of crescentic glomerulonephritis on kidney biopsy, might require addition of immunosuppressives.

GESTATIONAL COUNSELING DURING PREGNANCY IN PATIENTS WITH KIDNEY DISEASE: EXPERIENCE OF A MULTIDISCIPLINARY TEAM
Maria Verónica Coll Brito1, Gerson Berna Redondo1, Berta Magallares Lopez2, Elisa Llurba Olivé3,4,5, Xoana Barros5,6, Anna Dominguez1, Beatriz Bardaji7, Lluis Guirado1,5,8, Monserrat Díaz Encarnación1,4,5 and Helena Marco Rusiñol1
1Fundació Puigvert, Nephrology Service, Barcelona, Spain, 2Hospital de la Santa Creu i Sant Pau, Rheumatology Service, Barcelona, Spain, 3Hospital de la Santa Creu i Sant Pau, C/ de Sant Antoni Maria Claret, 16, Barcelona, Spain, 4Institut d’Investigación Biomèdica Sant Pau, Barcelona, Spain, 5Universitat autònoma de Barcelona, Spain, 6Universitat de Girona, Spain, 7Fundació Puigvert, Research Support Unit, Barcelona, South Sudan and 8Universitat de Vic, Spain

Background and Aims: Chronic kidney disease increases morbidity and mortality in pregnancy, being more prone to complications. Because it confers a risk to the fetus, this group of patients should be evaluated by a multidisciplinary unit, including nephrologists, rheumatologists, and obstetricians. Our study’s objective is to describe the clinical/analytical characteristics of patients with kidney disease (KD), assessed in a multidisciplinary consultation, to inform them of the risks and to be able to prepare them to reach pregnancy optimally. At the same time, detect patients with increased risk of complications and perform close follow-ups during pregnancy and postpartum.

Method: Demographic, clinical, analytical, and obstetric variables were collected in a retrospective study that included women with kidney disease (inflammatory/ autoimmune) between May 2020 to March 2022. In our hospital, the hereditary kidney disease unit offers reproductive advice to its patients, which was not considered in this study.

Results: A total of 24 patients with a median age of 35 years (18-39) were evaluated, classifying them into two independent groups: 1-pre-pregnancy (N=12) and 2-during pregnancy (N=12) and postpartum (N=10). All patients
from group 1 have kidney disease (100%). Lupus nephropathy (LN) was the most frequent (64%), followed by minimal change disease (17%) and IgA nephropathy (9%). Maternal-fetal risks were evaluated according to clinical and analytical parameters (age, blood pressure, renal function, proteinuria, and disease activity, among others). 17% of patients had a history of high blood pressure. Treatment modification was made in 25%. Renal biopsy was performed in 4/7 LN patients, and pregnancy was not recommended for one of them (class III LN). In group 2, 14% of the patients presented onset of disease one patient pre-rituximab therapy in LN and another one, an atypical hemolytic uremic syndrome in the immediate postpartum), the rest of them had previous KD: IgA Nephropathy (25%), and minimal change disease (17%), were the most frequent. 8% of the patients had a history of high blood pressure, 25% of them received ACE/ARBs that were discontinued. There were no cases of preeclampsia/eclampsia. The average gestation time was 38.3 weeks, 6.7% <37 weeks, and none <34 weeks. All newborns weigh greater than 2.5 Kg (mean birth weight 3.42 Kg). There were three inductions (two due to diabetes and one due to an altered topographic record). One peri-gestational complication (premature rupture of membranes) and one perinatal complication (respiratory distress) were observed. No other recorded/evidenced complications.

Conclusion: The gestational counseling and monitoring during pregnancy provide adequate support for patients with KD, being able to carry out a “guided” pregnancy with fewer complications. The strategies of our unit include modification of pre-conception treatment, activity control of underlying pathologies, and monitoring of kidney disease during pregnancy to reduce the risk of miscarriages, premature births, and low birth weight, among other complications.

#3767
THE IMPACT OF COVID-19 PANDEMICS ON THE OUTCOME OF 24 CHINESE PATIENTS DIAGNOSED OF MEMBRANOUS NEPHROPATHY RECEIVING RITUXIMAB THERAPY

Chao Li, Peng Xia, Hao-Yuan Cui, Hang Li, Yan Qin, Limeng Chen, Xueimei Li and Xuewang Li

Peking Union Medical College Hospital, Nephrology, Beijing, P.R. China

Background and Aims: Rituximab has been considered as the first-line immunosuppressive therapy in membranous nephropathy. Anti-CD20 depletion therapy is associated with prolonged B-cell depletion and has been reported to increase risk of severe COVID-19 infection in several rheumatic and neurologic diseases. However, few studies reported the impact of COVID-19 infection on membranous nephropathy in the status of B-cell depleletion. Our study aimed to describe the impact of prior rituximab therapy on clinical outcomes of a group of Chinese membranous nephropathy within 6-month follow-up during COVID-19 pandemics.

Method: We prospectively conducted a cohort study of adult patients diagnosed of membranous nephropathies receiving rituximab therapy from Aug 1st to Nov 30th in 2022, in one tertiary hospital, in Beijing. Patients’ baseline characteristics (including demographic data, serum albumin, serum creatinine, 24-hour proteinuria, serum IgG level, peripheral lymphocyte subsets, medications, past medical history, prior COVID-19 vaccination history), clinical outcomes were recorded. We followed up all the patient regularly until Jan 31st, 2023.

Results: We included 24 patients with median age of 55 (27, 83) years old. 13 (54.2%) patients were on chronic immunosuppression with corticosteroids, calcium urate inhibitors, and/or mycophenolate mofetil. We followed up the patients within median 4.6 months since last rituximab infusion at the dose of 1 gram. During follow-up, 18 (75%) patients got COVID-19 infection including 16 non-severe cases and two severe cases requiring hospitalization and treatment modification was made in 25%. Renal biopsy was performed in 4/7 LN patients, and pregnancy was not recommended for one of them (class III LN). In group 2, 14% of the patients presented de novo nephrotic syndrome and another one, an atypical hemolytic uremic syndrome in the immediate postpartum), the rest of them had previous KD: IgA Nephropathy (25%), and minimal change disease (17%), were the most frequent. 8% of the patients had a history of high blood pressure, 25% of them received ACE/ARBs that were discontinued. There were no cases of preeclampsia/eclampsia. The average gestation time was 38.3 weeks, 6.7% <37 weeks, and none <34 weeks. All newborns weigh greater than 2.5 Kg (mean birth weight 3.42 Kg). There were three inductions (two due to diabetes and one due to an altered topographic record). One peri-gestational complication (premature rupture of membranes) and one perinatal complication (respiratory distress) were observed. No other recorded/evidenced complications.

Conclusion: The gestational counseling and monitoring during pregnancy provide adequate support for patients with KD, being able to carry out a “guided” pregnancy with fewer complications. The strategies of our unit include modification of pre-conception treatment, activity control of underlying pathologies, and monitoring of kidney disease during pregnancy to reduce the risk of miscarriages, premature births, and low birth weight, among other complications.

SERUM PERIOSTIN IN KIDNEY TRANSPLANT RECIPIENTS AS A NOVEL BIOMARKER PREDICTING RENAL FUNCTION LOSS

Anna Kurnik1, Krzysztof Batko1, Katarzyna Krzanska1, Jolanta Malyszko1, Ewa Koc-Zorawska1, Marcin Zorawski2, Malgorzata Banaszkiewicz3, Karolina Woziwodzka1, Jacek Malyszko1 and Marcin Krzanski2

1Jagiellonian University Medical College, Department of Nephrology and Transplantation, Poland, 2Medical University of Warsaw, Department of Nephrology, Dialysis and Internal Medicine, Warsaw, Poland, 3Medical University of Bialystok, Second Department of Nephrology and Hypertension with Dialysis Unit, Bialystok, Poland, 4Medical University of Bialystok, Department of Clinical Medicine, Poland and 5Medical University of Bialystok, I Department of Nephrology, Dialysis and Transplantology, Bialystok, Poland

Background and Aims: Experimental studies have shown peristin is expressed throughout organogenesis, particularly within the kidney interstitium. Peristin is enhanced in different tissues of patients with nephropathy and has been considered as a candidate biomarker of kidney injury.

Method: Retrospective analysis of electronic medical record of one hundred and five kidney transplant recipients (KTRs) was performed. Only patients under sequential ambulatory care, with a history of at least 2 years post-transplant were included. Median (IQR) follow-up and time post-transplant was 4.42 (2.65, 4.58) and 4.29 (3.04, 8.07) years, respectively. Additionally, thirty-two health volunteers (HV) were enrolled. Biochemical testing was performed using commercially-available immunoassays.

Results: Median [IQR] serum peristin was significantly lower in KTRs as compared with HV (959 [732, 1204] vs. 1176 [997, 1408]; P<0.01). Higher serum peristin was observed in male patients (7.01 [6.84, 7.22] vs. 6.79 [6.64, 7.07], P<0.05) and a significant relationship was noted for interleukin 6 (IL6; r=0.24, P=0.01) and baseline estimated glomerular filtration (eGFR) (r=0.20, P=0.04). Patient age (P=0.60), body-mass index (P=0.08), cardiovascular disease (P=0.31), diabetes (P=0.45), current smoker status (P=0.27), nor anemia (P=0.25) were not associated with serum peristin. In a generalized additive model adjusted for baseline renal function and IL-6, serum peristin showed a significant nonlinear association (P=0.04) with eGFR change over follow-up.

Conclusion: Previous studies reported an association between peristin expression and the severity of histological injury within the kidney in both inflammatory and non-inflammatory conditions. Serum peristin may be a potential marker aiding in prediction of renal function in KTRs.
Background and Aims: The incidence of nephrolithiasis has risen in recent years, largely due to changes in diet and lifestyle. An association between nephrolithiasis and risk of cardiovascular disease has been described, including atherosclerosis. The underlying mechanisms linking the two conditions are not well understood, making it important to study the role of exercise and nutritional habits. This study aims to examine the incidence of cardiovascular comorbidities in patients with nephrolithiasis, considering demographic information and the timeline of disease diagnosis and follow-up. Conditions such as dyslipidemia, myocardial infarction, stroke, and metabolic syndrome are of particular interest in this population.

Method: We retrospectively analysed consecutive patients that were referred to our tertiary medical center nephrolithiasis clinic between 2021 and 2023. The demographic information collected included gender, age at first nephrolithiasis diagnosis, current age, and family history. The cardiovascular conditions analysed included metabolic syndrome, hypertension, diabetes, gout, smoking, stroke, and dyslipidemia. Additionally, renal function (GFR-EPI) was also taken into account. Appropriate tests for continuous and categorical variables were applied, recurring to SPSS v21.0.

Results: A total of 84 patients were included in the study. Of these, 51.2% (n=43) were women with a median age of 52 years (IQR: 13-83) and a median age of first nephrolithiasis diagnosis of 34 years (IQR: 9-75). The analysed comorbidities showed a high incidence of hypertension (n=35, 41.7%), obesity (n=33, 40.7%), dyslipidemia (n=50, 61%), and metabolic syndrome (n=20, 23.8%). Family history was identified in 37.3% (n=31) of patients, with a significant difference for men, where 64.5% (n=20) had a positive family history (p-value 0.033). The results showed a relationship between increased body mass index and younger age of first nephrolithiasis diagnosis (p-value 0.012) and lower renal function at diagnosis (p-value 0.005).

Conclusion: The diagnosis of nephrolithiasis requires a change in the patient’s diet and lifestyle, not only because of the risk of recurrence, but also because these patients are at a higher risk of developing serious cardiovascular events. This study highlights the high incidence of these comorbidities and underscores the importance of both the patient and the nephrologist being diligent in addressing these issues to achieve better kidney and overall health outcomes.

Figure 1: Crude Kaplan-Meier survival curve comparing dialysis-free survival among patients stratified into high and low serum periostin status groups. Cut-off is based on the middle tertile. Tick marks represent censored events. P-value is based on the log-rank test.
hematuria and 49.5% presented with gross hematuria, and 26.3% needed dialysis at presentation. The main associated causes of IgA nephropathy were liver disease in 46.3%, staphylococcal or streptococcal infections in 23.2%, autoimmune rheumatological disorders in 16.8%, respiratory tract disorders in 9.5% and inflammatory bowel disease in 4.2% of cases. 25 patients (26.3%) only received treatment of the cause, while 70 patients (73.3%) received an add-on therapy. 18 patients (18.9%) received as well cyclophosphamide and 20 patients (21.1%) mycophenolate. There were no differences in age, peak serum creatinine, proteinuria, hematuria, need of dialysis at presentation, histological parameters or associated comorbidities between patients treated with steroids ± immunosuppressants and patients who received supportive treatment. After a median follow-up period of 33 months, 28 patients (29.5%) progressed to ESKD and were on maintenance dialysis, and 32 patients (33.7%) died. There were no differences in progression to ESKD between immunosuppressed patients (28.6%) and those who only received treatment of the cause (32%, \( P = .747 \)). Survival analysis curves showed no significant differences between patients treated only with supportive measures and those who received an add-on steroid and/or immunosuppressive therapy in regards of renal survival (log-rank = 0.003, \( P = .956 \)) or overall survival (log-rank = 0.871, \( P = .351 \)). Cox regression analysis showed that the only factor associated with renal survival was serum creatinine at presentation (HR 3.09, 95%CI 1.39-6.86) independent from age, hematuria, hypertension, diabetes or the use of steroids and/or immunosuppression.

**Conclusion:** Secondary IgAN that presents with acute kidney injury or rapidly progressive glomerulonephritis has a poor prognosis, particularly when diagnosis is delayed at presentation. Adding steroid treatment with or without immunosuppression to supportive measures and treatment of the cause of secondary IgA nephropathy is not associated with an improved renal or patient survival.

---

**#6213 RISK FACTORS FOR END-STAGE RENAL DISEASE IN IGA NEPHROPATHY**

**Bouassida Sahar, Meriam Khadrar, Hadded Sarra, Mouna Jerbi, Gaied Hanen, Aoudia Raja and Goucha Rym**

Hôpital Mongi Slim, Department of Nephrology, Marsa, Tunisia

**Background and Aims:** Immunoglobulin A nephropathy (IgAN) is the most common primary glomerular nephropathy worldwide and one of the principal causes of chronic kidney disease. The presentation of this nephropathy is different between ethnic groups. The aim of our work is to describe the clinical, biological, and pathological symptoms of maghrebian patients diagnosed with IgAN.

**Method:** We conducted a retrospective descriptive study over 46 years from 1975 and 2021. This study included 213 patients with renal biopsy-proven IgAN whose clinical, biological, and pathological data were assessed and classified according to the Oxford classification.

**Results:** The mean age of the patients was 34.8 ± 15-80 with male predominance (sex ratio 1.77). Thirty-nine patients had a family history of kidney disease. 109 patients (51%) had hypertension. The median proteinuria was 2.6 g/24 h [0-46.17 g/24 h], Nephrotic proteinuria (>3 g/24h) was found in 98 patients (46%). The initial median glomerular filtration rate was 33.9 ml/min/1.73 m²/SC. At the end of the follow-up, it was 23.7 ml/min/1.73 m²/SC. Renal biopsy was performed in all the cases. The lesions observed in optical microscopy were mesangial proliferation M1 (63.8%), endocapillary proliferation E1 (8.5%), glomerulosclerosis S1 (71.4%), interstitial fibrosis or tubular atrophy T1-T2 (72.8%) and crescents C1 (16.9%). Fifty-two percent of the patients were managed conservatively whereas 9 (41%) were receiving immunosuppressive (steroid + mycophenolate mofetil) treatment.

**Conclusion:** Secondary IgAN that presents with acute kidney injury or rapidly progressive glomerulonephritis has a poor prognosis, particularly when diagnosis is delayed at presentation. Adding steroid treatment with or without immunosuppression to supportive measures and treatment of the cause of secondary IgA nephropathy is not associated with an improved renal or patient survival.

---

**#2954 DAPAFLIJLOZIN IN IGA NEPHROPATHY: EARLY EXPERIENCE FROM A SINGLE CENTER IN CENTRAL INDIA**

**Manish Balwani¹, Umesh Godhani², Amit Pasari¹, Amol Bhawane¹, Priyanka Tolani¹ and Shubham Dubey⁵**

1Saraswati Kidney Care Center (A unit of SS Multispeciality Hospital), Nagpur, India, ²Deshaya Kidney Hospital, Nephrology, Ahmadabad, India, ³AIIMS, Nagpur (All India Institute of Medical Sciences, Nagpur), Nephrology, Sumantha, India, ⁴Jawaharlal Nehru Medical College, Wardha, internal medicine, Wardha, India and ⁵Jawaharlal Nehru Medical College, Wardha, Nephrology, Wardha, India

**Background and Aims:** IgA nephropathy (IgAN), a common glomerulopathy, may progress to end-stage kidney disease despite use of optimum treatment with immunosuppressants and renin-angiotensin aldosterone system antagonists. Recently, dapagliflozin (DAPA) has been shown to reduce the progression of kidney function decline in IgAN. The beneficial effects in kidney function could be because of reduction in the intraglomerular pressure. To assess the kidney function in terms of change in estimated glomerular filtration rate (eGFR) and urinary protein creatinine ratio (UPCR) with use of DAPA in patients with IgAN.

**Method:** We retrospectively collected the data of IgAN patients from our electronic database. Demographic, renal function parameters and biopsy findings were collected and compared in patients who received immunosuppression only (group I) and those who received DAPA in addition to immunosuppression (group II).

**Results:** We identified a total of 150 patients with IgAN from our database. Among these, 59 (39.3%) were managed conservatively whereas 91 (60.7%) were receiving immunosuppressive (steroid + mycophenolate mofetil) treatment.

**Conclusion:** Our initial experience in patients of IgA nephropathy suggests that the addition of DAPA to existing immunosuppressive treatment is useful in reducing the UPCR in short-term.

**DISAPPEARANCE OF GLOMERULAR C3 DEPOSITION MIGHT BE A PROGNOSTIC MARKER IN MEMBRANOUS NEPHROPATHY AFTER TREATMENT**

**Byoung-Soo Cho, Sung Min Jung, Won Hee Cho and Hyunsook Lee**  
Rep. of South Korea

**Background and Aims:** Membranous nephropathy (MN) is the most common cause of nephrotic syndrome (NS) in adults. In about 80% is primary and remaining 20% are secondary due to medications or other diseases. Treatment of primary MN remains controversial, and the prognosis is still difficult to predict despite the introduction of anti phospholipase A2 receptor (PLA2R) antibody. We evaluated pathological changes for predicting prognosis in patients of MN after methyprednisolone (MPD) pulse therapy.

**Method:** We performed 1,649 renal biopsies at the OPD during last 9 years, of which 31 subjects were MN. We performed follow up biopsy who showed normal urinary findings after treatment with MPD pulse therapy in 11 subjects of MN. Indications of the initial biopsy in MN were oral steroid resistant NS (9 subjects), massive proteinuria associated with hematuria (2 subjects). Among the 11 subjects of MN, 3 subjects were lupus nephritis (LN), 8 subjects were primary MN. One cycle of MPD consist of 10-20 mg/kg (max 1.0 g/day) for 3 consecutive days, performing every 10 to 14 days. Mean MPD pulse therapy were done 13 cycles

**Results:** Among the 11 cases of MN, male to female ratio was 6 to 5. Age distribution from 1 year old to 61years old (mean 40.8 y/o), Mean spot urine protein to creatinine before treatment was 4,182.5 mg/g and 189.4 mg/g after treatment, 9 subjects showed glomerular C3 deposition were noted at the initial biopsy and 2 subjects showed no C3 deposition. After treatment glomerular C3 deposition were disappeared in 8 subjects, and showed no relapse during 5.3 years follow up. However, 3 subjects who showed glomerular C3 deposition were lupus nephritis, relapsed during follow up period.

**Conclusion:** MPD pulse therapy might be still promising therapeutic modality in conventional oral steroid resistant MN. Although further larger number of studies are mandatory, disappearance of glomerular C3 deposition might be a prognostic marker for treatment response, instead of disappearance of proteinuria in MN.

#6929
**SGLT2 INHIBITORS IN IGA NEPHROPATHY: REAL LIFE EXPERIENCE AT OUR CENTRE**

**Renata Carvalho1, Joana Medeiros1, Olga Pires2, José Mário Bastos1, Bárbara Ribeiro1, Johanna Rodrigues Viana1, Raquel Vaz1 and Sofia Homem Melo Marques2**  
1Braga Public Hospital, Nephrology, Braga, Portugal and 2Braga Public Hospital, Internal Medicine, Braga, Portugal

**Background and Aims:** SGLT2 inhibitors (SGLT2i) have a beneficial effect in diabetic and non-diabetic proteinuric chronic kidney disease (CKD), demonstrated in large randomized controlled trials. However, there is limited information about real life experience with SGLT2i in non-diabetic CKD like IgA nephropathy (IgAN).

**Method:** All patients with biopsy-proven IgA nephropathy since 2015 were evaluated for SGLT2 use. We collected data on age, gender, the use of renin-angiotensin-aldosterone system inhibitors (RAASi), eGFR, glycosuria and proteinuria at baseline, at 6 months and at one year of follow-up. Glomerular filtration rate (eGFR) was estimated using the CKD-EPI equation. Data was analyzed using Iamovi®.

**Results:** 51 patients had IgAN diagnosed by kidney biopsy from April 2015 until March 2021. Eleven of these started SGLT2i between December 2020 and February 2022 (at their physician’s description). Their median age was 52, nine were male and all were taking RAASi. The initial median proteinuria was 1 g/g (range 0.5-2.0 g/g), median eGFR was 57.5 mL/min (range 16.8-104 mL/min). At 6 months, the median proteinuria was 0.7 g/g (range 0.8-4.8 g/g), median eGFR was 42.6 mL/min (range 13.9-108 mL/min). One year after beginning SGLT2i, 8 patients have laboratory values and the median value of proteinuria was 0.85 g/g (range 0.2-3.0 g/g) and the median eGFR was 40.5 mL/min (range 14.5-85.4 mL/min). All patients had glycosuria at all urine evaluations confirming no discontinuations of the SGLT2i. No serious adverse events were reported and none of the patients needed dialysis or died. There were no significant differences between proteinuria and eGFR between evaluations at the start, 6 months and 1 year of follow-up.

**Conclusion:** SGLT2i have become important drugs in IgAN. Our first cases who started SGLT2i showed good compliance (using glycosuria as an indirect tool to monitor adherence) and no adverse events, irrespective of their initial eGFR. The small sample was probably a limitation to the lack of significant results.

#6930
**TOO ELDERLY FOR A KIDNEY BIOPSY?**

**Joana Medeiros, Renata Carvalho, José Mário Bastos, Johanna Rodrigues Viana, Sofia Homem Melo Marques, Raquel Vaz and Rui Costa**  
Hospital de Braga, Serviço de Nefrologia, Braga, Portugal

**Background and Aims:** As we age, we lose kidney function and accumulate risk factors and comorbidities that predispose to kidney damage. However, kidney disease can develop at any time. Life expectancy continues to improve worldwide. For that reason, more elderly patients are undergoing diagnostic kidney biopsies (KB). There is a general reluctance in performing KB in those patients. It is important to know if a diagnosis KB in elderly patients can have a positive therapeutic impact.

**Method:** In this retrospective cohort study, we analyzed the medical charts of all patients aged ≥ 80 years who underwent a native kidney biopsy (KB) between January and December 2021, in a central hospital in Portugal.

**Results:** Between January and December 2021, 59 patients underwent a native KB, 6 of them over 80 years of age (10% of all patients). Between those elderly patients, the median age was 82 years. The indications for KB were chronic kidney disease with a nephrotic range proteinuria in 3 patients, nephrotic syndrome, acute glomerulonephritis and acute kidney injury in 1 patient each. Median serum creatinine was 2.27 mg/dL (minimum 0.8 and maximum 5.4 mg/dL) and median protein-to-creatinine ratio was 5.7 g/g (minimum 3.3 and maximum 13g/g). The pathological diagnoses found were focal and segmental glomerulosclerosis (FSGS) (n=2), pauci-immune crescentic glomerulonephritis (n=1), membranous nephropathy in a patient with a follicular lymphoma (n=1), acute interstitial nephritis (AIN) (n=1), and diabetic glomerulosclerosis in a patient with a monoclonal gammapathy of undetermined significance (n=1). 3 patients have received a kidney-specific treatment – the patient with AIN started corticosteroids, one patient with FSGS was submitted to corticosteroids plus tacrolimus, and the patient with pauci-immune crescentic glomerulonephritis plus rituximab. The patient with membranous nephropathy and follicular lymphoma received a specific chemotherapy regimen according with lymphoproliferative disease. An improvement in kidney function occurred only in one patient and the other three developed adverse effects (particularly corticosteroids induced diabetes and infections). One year later, one of patients who received treatment was dead, another one was on hemodialysis, and the other two patients had a glomerular filtration rate lower than 15mL/min/1.73 m².

**Conclusion:** Elderly patients have a higher risk of adverse effects from the kidney-specific treatment. It is important to assess the therapeutic risk/benefit when considering performing a renal biopsy in these patients.
CHRONIC KIDNEY DISEASE

C1 - BASIC SCIENCES & EXPERIMENTAL

COMPLEMENT C3 EXERTS DIRECT PRO-FIBROTIC EFFECTS ON KIDNEY TUBULES

Anna Manzéger, Rita Bencs, Kristzina Fazeikas, Ganna Stepanova and Gabor Kokeny
Semmelweis University, Institute of Translational Medicine, Budapest, Hungary

Background and Aims: Renal complement expression has been observed in both experimental and human kidney diseases. We have previously reported massive tubular C3 expression in fibrotic TGF-beta1 transgenic mice (Nephrol Dial Transplant 2015, 30; S3:FP301). Still, little is known whether this intra-renal complement is only an inflammatory marker of renal fibrosis or also exerts direct pro-fibrotic effects in the pathogenesis. In the present study we aimed to investigate the effect of C3a receptor activation in murine primary tubular epithelial cells.

Method: Primary tubular epithelial cells (TEC) were isolated from kidneys of four-weeks-old male C57Bl6 mouse. The cells were grown in DMEM/12 medium supplemented with 2% FBS and recombinant 5 ng/ml EGF, and characterized for epithelial and mesenchymal markers. Verified TEC cells were seeded on 6-well plates and treated for 24 hours with PBS (CTL, n = 3), 100 nM C3a receptor agonist peptide (C3aR, n = 3) or 10 ng/ml recombinant TGF-beta1 (TGFb, n = 3). Then, mRNA and protein expressions were assessed and evaluated using Kruskal-Wallis test (p < 0.05).

Results: TGF-beta induced a 2-fold Col1a1 and 1.6-fold Tgfb1 mRNA expression, accompanied by 4-fold Egr2 but not affect Ccl2 or C3 mRNA expression. In contrast, C3aR group depicted 1.6-fold C3 and 1.8-fold Ccl2 mRNA expression, an only 1.6-fold Egr2 but a 2-fold Col1a1 and 1.5-fold Tgfb1 mRNA expression. Despite the similar Tgfb1 mRNA overexpression in TGFb and C3aR groups, marked Tgfb1 protein overexpression (15-fold) was only observed in TGF-beta treated cells but not in the C3aR group.

Conclusion: Our study data indicate that renal complement C3 production can exert autocrine / paracrine direct pro-fibrotic effects on tubular epithelial cells unrelated to TGF-beta protein levels. Therefore, local C3 overexpression might play a significant pathogenetic role in kidney fibrosis.

MILD EXPERIMENTAL CKD IS ASSOCIATED WITH MYOCARDIAL FIBROSIS AND NOTCH/HEDGEHOG SIGNALING DYSREGULATION

Evdokia Bogdanova1, Airat Sadykov2, Olga Beresneva1, Vladimir Sharoyko3 and Vladimir Dobronravov4
1Pavlod University, Research Institute of Nephrology, Russia, 2Pavlod University, Raisa Gorbacheva Memorial Research Institute for Pediatric Oncology, Hematology and Transplantation, Russia and 3Pavlod University, Department for General and Bioorganic Chemistry, Russia

Background and Aims: Chronic kidney disease (CKD) is an independent cardiovascular risk factor. The initial mechanisms of myocardial remodeling (MR) in CKD are poorly understood. The major developmental signaling pathways Notch, Hedgehog, Wnt, and Bmp seem to be involved in many crucial steps of MR (cardiomyocytes survival and regeneration, fibrotic response, angiogenesis), while their role in MR due to CKD was not previously studied.

Phosphate (Pi) is essential for cellular signaling and its redistribution to the cardiovascular compartment in CKD could be one of the mechanisms of MR. Here we investigated the involvement of Pi/PPI transport, and reactivation of developmental signaling pathways in myocardial alterations associated with mild CKD.

Method: We induce mild CKD by 3/4 nephrectomy in adult male SHRs (SHR-Nx, n = 8) with normal phosphate intake (0.6%) and 2-month follow-up. Controls were sham-operated SHR (SHR-Sham, n = 8) and Wistar Kyoto rats (WKY-Sham, n = 8). We analyzed chronic kidney injury and Pi exchange parameters, serum intact parathyroid hormone (PTH), intact fibroblast growth factor 23 (FGF23), myocardial phosphorus content (ICP-AES), histomorphometry, PTV1 and PTV2 expression (IHC), and mRNA expression of Slco2a1, Slc20a2, Ankh, Mapk1, Mapk3, Bmp2, Bmp4, Cinnb1, Fzd2, Sfrp2, Dkk1, Wif1, Numb, Notch1, Jag1, Hes1, Lgr4, Tnfα, Tgfb1, and Ppil mRNA expression (Figure 2). We found no changes in Slco2a1 and Slc20a2 mRNA levels (Figure 2). An appearance of PTV2-positive fibroblasts-like cells in myocardial interstitium was apparent in SHR-Nx rats (data not shown).

Conclusion: Myocardial alterations in mild CKD are manifested in an increase in its phosphorus content, interstitial fibrosis, and dysregulation in genes likely related to the induction of the myofibroblasts and extracellular matrix remodeling.

Abstract i1153
BACKGROUND AND AIMS: Autologous mesenchymal stem/stromal cells (MSCs) have emerged as a therapeutic option for many chronic diseases. Hypertensive kidney disease (HKD) might impair MSCs’ reparative ability by altering important biomolecular properties of the cell, but the characteristics of this impairment are unclear. In our previous pre-clinical studies, hypoxic preconditioning (HPC) enhanced MSC angiogenesis and reduced senescence through global gene and protein expression. Thus, we hypothesize that HPC would improve human MSCs by enhancing their functionality and angiogenesis, creating an anti-inflammatory and anti-senescence environment in MSCs from healthy control (HC), hypertensive patients (HTN), and hypertensive kidney disease patients (HKD).

METHOD: Human MSCs were collected from abdominal subcutaneous fat tissue biopsy of HC, HTN, and HKD patients (n=12 each). Samples were collected from healthy volunteers with no history of hypertension or kidney disease (HC), patients diagnosed with hypertension controlled with antihypertensive drugs (HTN), and hypertensive patients with eGFR<60 mL/min/1.73 m² (HKD). MSCs were harvested and cultured in Normoxic (20% O₂) or Hypoxic (1% O₂) conditions for 24-48 hours. MSC functionality was measured by migration and proliferation. Angiogenic and inflammatory secretome in conditioned media was assessed along with MSC senescence by senescence-
associated beta-galactosidase (SA-beta-gal) activity. In addition, transcriptome analysis using RNA-sequencing (n=3/group) and quantitative PCR (qPCR) were performed to evaluate gene expression.

**Results:** At baseline, Normoxic HTN-MSCs interestingly had higher proliferation compared to HC. HC-MSC subjected to HPC showed increased proliferation (Figure 1A). SA-β-gal activity tended to decrease after HPC, particularly in the HC group (P = .06). HPC did not affect the release of the pro-angiogenic protein VEGF from MSCs, but increased EGF in HC-MSC, and decreased HGF in HC and HKD-MSCs. HPC upregulated the pro-angiogenic genes, inflammatory gene, and a few senescence genes (Figure 1F).

**Conclusion:** HPC has a more favorable functional effect on HC- than on HKD-MSC, reflected in increased proliferation and EGF release, and tends to decrease senescence, whereas it has little effect on HTN or HKD-MSCs. These observations may assist in developing novel therapeutic strategies to improve the regenerative capacity of MSCs in patients with hypertensive kidney disease.

**LOSS OF NLRP6 INCREASES THE SEVERITY OF KIDNEY FIBROSIS**

Lara Valiño1, Chiara Favero 2, Aranzazu Pintor-Chocano2, Sol Carriazo2, Alberto Ortiz2 and Maria Dolores Sanchez-Nino2

1IIS Fundacion Jimenez Diaz, Nephrology, Madrid, Spain and 2IIS-Fundacion Jimenez Diaz, Nephrology, Madrid, Spain

**Background and Aims:** The burden of chronic kidney disease (CKD) is growing worldwide, illustrating the need for better prevention and therapeutic approaches. Kidney fibrosis is a hallmark of CKD that is not specifically addressed by current therapeutic options. The nucleotide-binding oligomerization domain-like receptor (NLR) family has 22 members. The NLRP3 inflammasome has been most extensively studied in the context of kidney disease where it plays a pathogenic role. However, the role of NLRP6 during CKD and kidney fibrosis remains unexplored. The aim of the study was to explore the role for endogenous Nlrp6 in protecting from kidney fibrosis.

**Method:** A hypothesis-driven analysis of non-biased human kidney disease transcriptomics databases was performed to identify NLRs other than NLRP3 of potential therapeutic interest, based on differential gene expression during CKD and the relationship of gene expression to severity of CKD. We explored Nlrp6 expression in preclinical accelerated CKD and kidney fibrosis (UUO) and characterized the function of endogenous Nlrp6 by inducing UUO in Nlrp6-deficient mice and validated the results in a second model of kidney fibrosis. Once tubular cells were identified as the key cells expressing NLRP6 and regulating Nlrp6 expression during UUO, we explored the drivers of Nlrp6 downregulation in tubular cells, as well as the consequences of Nlrp6 downregulation in these same cells.

**Results:** The role of Nlrp6 in experimental CKD was explored in wild-type and Nlrp6-deficient mice with unilateral ureteral obstruction (UUO). Whole kidney Nlrp6 mRNA and tubular cell Nlrp6 protein decreased following UUO. Low kidney Nlrp6 immunostaining was also observed in human CKD. Genetic Nlrp6 deficiency resulted in increased kidney p38 MAP kinase activation and more severe kidney inflammation and fibrosis, as assessed by kidney inflammatory gene expression, interstitial macrophage infiltration, expression of profibrotic cytokines and extracellular matrix encoding genes, Smad3 phosphorylation, Sirius red staining, collagen, and fibronectin deposition and myofibroblast numbers. Similar results were obtained in adenine-induced kidney fibrosis. Cytokines involved in the pathogenesis of kidney fibrosis, such as the profibrotic cytokine TGF-β1 and the proinflammatory cytokine TWEAK, decreased Nlrp6 expression in cultured tubular cells, while siRNA targeting Nlrp6 resulted in increased TGF-β1 and CTGF expression, which was limited by inhibiting p38 MAPK.

**Conclusion:** In conclusion, endogenous constitutive Nlrp6 dampens sterile kidney inflammation and fibrosis likely by dampening tubular cell responses. Loss of Nlrp6 expression may contribute to CKD progression.

**CLINICAL-FUNCTIONAL KIDNEY-LUNG LINK IN A POPULATION OF HEMODIALYZED PATIENTS**

Ersilia Satta1,2, Carmine Romano1, Ilaria Raiola1, Anna Scafarto2, Sandro Gentile1, Gioacchino Erbaggio1, Guido Gembillo3 and Mario Polverino4

1Nephrology and Dialysis Center, Nephrology and Diabetology Research, Naples, Italy, 2Nefrocenter Research S.crl, Nephrology and Diabetology Research, Naples, Italy, 3Institute of Nephrology The University of Messina, Institute of Nephrology, Messina, Italy and 4Nephrology and Dailyis Research, Nefrocenter, Naples, Italy

**Background and Aims:** We know that lung and kidney are intimately related from a functional standpoint, both in physiological conditions and in diseases. The close relationship between lung and kidney (kidney-lung link) is evidence of a homeostatic connection between all organs and systems in an attempt to maintain the body system balance. In a recent review [1] we emphasized the importance to search for the clinical signs of a disease not only in the primary affected organ but also in organ functionally related.

**Method:** For this purpose we examined 81 hemodialyzed patients, with a mean age of 66.6 ± 13 years (28 f and 53 M), undergoing hemodialysis treatment

**PERLECAN AS A POTENTIAL BIOMARKER OF CARDIOVASCULAR RISK: ROLE OF ENDOTHELIAL GlicoCaLyX IN CHRONIC KIDNEY DISEASE**

**Gemma Valera Arévalo¹, Andrea Figuer Rubio², Paula Jara Caro Espada³, Claudia Yuste¹, Enrique Morales³, Noemi Ceprian Costoso¹, Guillermo Bodega¹, Rafael Ramirez², Matilde Alique² and Julia Carracedo¹**

¹Instituto de Investigación Sanitaria Hospital 12 de Octubre (imas12), Department of Genetics, physiology and microbiology, Biological science, Universidad Complutense de Madrid, Spain, ²Instituto Ramón y Cajal de Investigación Sanitaria (IRYCSIS), Department of Systems Biology, Universidad de Alcalá, Spain, ³Instituto de Investigación i+12, Department of Nephrology, Hospital Universitario 12 de Octubre, Spain, ⁴Instituto de Investigación Sanitaria Hospital 12 de Octubre (imas12), Department of Medicine/Department of Nephrology of Hospital de Octubre de Madrid, Spain and ⁵Department of Biomedicine and Biotechnology, University of Alcalá, Spain

**Background and Aims:** Chronic kidney disease (CKD) is associated with cardiovascular disease (CVD). CVD is in turn related to endothelial dysfunction, endothelial dysfunction, and degradation of the endothelial glyocalyx (EG), releasing its components into the bloodstream. The EG consists of glycosaminoglycans and proteoglycans, such as Perlecan. The aim of the study is to analyse the levels of perlecan in plasma in different stages of CKD and to relate them to age and inflammatory monocytes, as well as their adhesion capacity (CD54/ICAM-1).

**Method:** An observational cross-sectional study was carried out. 56 patients were included: advanced chronic kidney disease (ACKD) (n=13), haemodialysis (HD) (n=13), peritoneal dialysis (PD) (n=15) and transplant recipients (TX) (n=15). Thirty healthy subjects (CT) were analysed. Plasma perlecan levels were quantified using ELISA and phenotyping of monocyte subpopulations (classical (CD14+CD16+), intermediate (CD14+CD16+) and non-classical (CD14+CD16+)), as well as CD54 (ICAM-1) expression by flow cytometry. Statistical analysis: ANOVA and Spearman correlation.

**Results:** The mean values of PFT were globally no different between smokers with normal PFT and non smokers are summarized in Table 1: Although the never-smoking group was nearly twice as large as the smokers, and PFT were similar and normal, respiratory symptoms were predominant: daily cough (49 yes; 26 no); chronic phlegm (51 yes; 24 no).

**Conclusion:** In dialysis patients, cough and phlegm are common symptoms, regardless of smoking and spirometric values. Probably these results are the consequence of synergistic effects between lungs and kidneys, as recently demonstrated [2]. Hence the need to evaluate dialysis patients from the clinical-functional point of view of both, kidneys and lungs, in order to evaluate the appropriate, personalized, therapeutic strategy according to the last evidences of the literature [3].

**NOVEL ASPECT OF NATURAL FLAVONOL Fisetin VIA INHIBITING ACSL4-MEDIATED TUBULAR FERROPTOSIS AGAINST FIBROTIC KIDNEY DISEASE**

**Bo Wang, Letian Yang, Liang MA and Ping Fu**

West China Hospital, Sichuan University, Division of Nephrology, Kidney Research Institute, Chengdu, P.R. China

**Background and Aims:** Kidney fibrosis is the hallmark of chronic kidney disease (CKD) progression, whereas no effective anti-fibrotic therapies exist. We previously reported that natural flavonol fisetin alleviated septic acute kidney injury and protected against hyperuricemic nephropathy in mice. However, the versatile role and potential mechanism of fisetin against fibrotic kidney disease have not been well characterized. Recently, tubular ferroptosis contributes to the pathogenesis of CKD with a persistent inflammatory and profibrotic response.

**Method:** Here, we found that fisetin significantly improved tubular injury, as well as CD54 (ICAM-1) expression on monocytes, which is important for its contribution to the pathogenesis of CKD with a persistent inflammatory and profibrotic response.

**Results:** Patients with CKD had higher plasma levels of perlecan than healthy participants (p-value = 0.044 vs ACKD, 0.028 vs HD and 0.002 vs PD) (Fig. 1). These levels were associated with higher percentage of classical monocytes (p=0.011) intermediate monocytes (p=0.009) and non-classical monocytes (p=0.003) expressing ICAM-1 but not with a higher expression of ICAM-1 per monocyte. Perlecan levels correlate negatively with age (p=0.03) (Table 1).

**Conclusion:** Patients with ACKD, HD and PD have elevated plasma perlecan levels compared to CT and TX. Elevated perlecan concentrations are associated with increased ICAM-1 expression on monocytes, which is important for its possible role in the development of atherosclerosis. Perlecan may be postulated as a molecule of interest to assess endothelial and cardiovascular damage in CKD patients.

**Table 1: Correlation between perlecan levels in plasma, age and ICAM-1 expression in monocytes. MFI: mean fluorescence intensity. Pearson correlation test was performed. Statistical significance was denoted by *p<0.05.**

**Figure 1:** (A) Perlecan plasma levels (ng/mL) in healthy subjects (HS), patients with advanced chronic kidney disease (ACKD); hemodialysis treatment (HD); peritoneal dialysis (PD) and patients with kidney transplantation (TX). *p < 0.05, **p < 0.01 vs CT; †p < 0.05 vs PD. Statistical analysis: Kruskal–Wallis test for perlecan (non-parametric).
Results: Mechanistically, fisetin inhibited ferroptosis in the kidneys of CKD mice as well as in injured tubular epithelial cells, as evidenced by a decrease of ACSL4, COX2, HMGB1, and an increase of GPX4. Meanwhile, fisetin effectively restored ultrastructural abnormalities of mitochondrial morphology and relieved the elevated iron, the downregulated GSH and GSH/GSSG, as well as the upregulated lipid peroxide MDA in the kidneys of CKD mice. Notably, abnormal expression of ferroptosis key marker ACSL4 was verified in renal tubules of CKD patients (IgAN, MN, FSGS, LN, and DN) and mice (adipine and UUO), which was also observed in injured tubular cells. Furthermore, ACSL4 knockdown inhibited tubular ferroptosis, while ACSL4 overexpression blocked anti-ferroptotic effect of fisetin and reversed the cytoprotective, anti-inflammation, and anti-fibrosis of fisetin in injured tubular cells.

Conclusion: In summary, we for the first time explored a novel aspect of fisetin via inhibiting ACSL4-mediated tubular ferroptosis against fibrotic kidney diseases.

A NOVEL ELECTRO-HYDRAULIC ACOUSTIC THERAPY REDUCES BLOOD PRESSURE IN HYPERTENSIVE PATIENTS WITH CHRONIC KIDNEY DISEASE: PRELIMINARY RESULTS

Talya Wolak1,2, Amir Lerman3, Michael Glikson1,2, Ivetta Sukholutsky2, Shuli Silberman2 and Lilach Lerman3
1Faculty of Medicine, The Hebrew University of Jerusalem, Jerusalem, Israel, 2Shaare Zedek Medical Center, Jerusalem, Israel and 3Mayo Clinic, Rochester, United States of America

Background and Aims: Arterial hypertension (HTN) in association with chronic kidney disease (CKD) is a global healthcare burden, yet clinically proven treatments are limited. electro-Hydraulic Acoustic Therapy (eHAT), using ~10% of the energy used in shockwave lithotripsy, is a promising technique which was also observed in injured tubular cells. Moreover, eHAT has been demonstrated to enhance healing in tissues such as bone, muscle, and myocardium, via several mechanisms, particularly by promoting neovascularization. Furthermore, previous animal studies demonstrated that eHAT reduces blood pressure (BP) and preserves renal function after ischemic kidney injury. The present pilot study explored the clinical safety and efficacy of eHAT and tested the hypothesis that eHAT would reduce BP and preserve renal function in patients with medically-treated hypertension and CKD.

Method: So far, a total of 15 patients with HTN and Stage III a/b CKD were enrolled in this prospective, single-arm study. The patients were treated with six sessions of eHAT during a 3-week period. At each session, 2400 shockwaves were applied to each kidney with 0.9 mJ/mm2 at 2.66Hz (NephrospecTM by Curespec LTD, Yehud, Israel). Follow-up (FU) visits were performed at 1, 3, and 6 months.

Results: The treatment was well tolerated with no major adverse events or need for analgesic treatment. Average Automated Office BP (AOBP) showed a strong tendency for a decrease in diastolic BP from baseline to the Primary Efficacy Objective at FU II (3 months post last treatment), which progressively decreased further at FU III (6 months) (Table 1). Similarly, average Office BP (OBP) detected a strong trend for a progressive decrease in systolic BP from baseline to the Primary Efficacy Objective (Table 1). Levels of eGFR appeared to slightly rise throughout the study, but this change has not reached statistical significance levels (Table 1).

Conclusion: The current study demonstrates that the eHAT procedure is tolerable and safe in this cohort. Moreover, a 3-week regimen tended to reduce BP and preserve eGFR in patients with controlled HTN and CKD. Therefore, electro-Hydraulic Acoustic Therapy may emerge as a novel, safe, and non-invasive alternative therapeutic approach in the management of HTN in the context of CKD.

VOLUNTARY EXERCISE EXACERBATES CHRONIC KIDNEY DISEASE INDUCED BY FOLIC ACID IN MALE C57BL/6 MICE

Raisa Brito Santos1, Gabriel Estrela2, Alexandre Budu1, Adriano Arruda1 and Ronaldo Araujo1
1Federal University of São Paulo Unifesp, Nephrology, São Paulo, Brazil, 2Biophysics, São Paulo, Brazil

Background and Aims: Voluntary exercise is of utmost importance to avert a plethora of diseases and to ameliorate other conditions, such as neuromuscular diseases, however in some occasions, the inflammation can be exacerbated by intense physical activity. The folic acid kidney disease model is of key interest since it is non-invasive and leads to conspicuous fibrosis. Our main objective was to determine the influence of voluntary exercise on chronic kidney disease in folic acid-treated mice.

Method: Male C57Bl6 mice were divided into 3 groups, vehicle (V), folic acid (FA), and folic acid + voluntary exercise (FA + E). The animals were kept in cages with or without voluntary wheels (sedentary or exercised groups) for 30 days, and then received a single injection of folic (240 mg/kg i.p.) in 0.3 mol/L sodium bicarbonate. The animals were euthanized after 28 days.

Results: Chronic kidney disease in the folic acid model is exacerbated by voluntary exercise. Voluntary exercise decreases the survival level in animals treated with folic acid (V- 100%, FA- 85,71%, FA + E- 60%). On day 28 after folic acid administration the urea levels (FA vs. FA + E P= 0.003) and creatinine (V vs. FA + E P= 0.0004; FA vs. Fa + E p= 0.0001). Renal injury marker such as KIM-1 (V vs. FA + E p= 0.00131, FA vs. Fa + E p= 0.0213) was higher in animals that went to the wheel, but NGAL showed no significant differences. Inflammation markers as IL-6 (V vs. FA + E p= 0.0037 FA vs. Fa + E p= 0.0254) and TLR4 (V vs. FA + E p= <0.0001 FA vs. Fa + E p= <0.0001) were exacerbated as well as apoptosis relation BAX/BCL2 (V vs. FA + E p= 0.0001 FA vs. Fa + E p= <0.0001). Picrosirius red staining was used to assess tubulointerstitial fibrosis and the kidney architecture; animals from the FA + E group showed the highest destruction of kidney architecture.

Conclusion: We established that previous voluntary exercise has deleterious effects on nephrotoxic folic acid–Induced CKD.
COMPENSATORY HYPTERTROPHY OF THE KIDNEY CONTRIBUTES TO LOSS OF KLOTHO KIDNEY THROUGH PAKT SIGNALING

Aurora Pérez-Gomez, Juan Miguel Díaz-Tocados, Juan Diego Domínguez Coral, Maite Caus Enríquez, Alicia García-Carrasco, Ana Martínez Bardají and José Manuel Valdivielso Revilla

IRB Lleida, Experimental Nephrology, Lleida, Spain

Background and Aims: Chronic kidney disease (CKD) represents a significant public health burden worldwide, mainly driven by the increase of the incidence of associated risk factors like diabetes. Decreased renal Klotho expression is an early feature of CKD, driving an increase on circulating FGF23 and phosphate. These alterations in mineral metabolism have a direct negative impact on the progression of renal dysfunction and can cause bone alterations, vascular calcification and heart failure. In parallel, during the early stages of CKD, kidneys activate molecular mechanisms of hypertrophy in an attempt to counteract the loss of renal function. The PI3K/Akt/mTOR pathway, activated by growing factors like insulin-like growing factor-1 (IGF-1) participates in compensatory renal growth. The aim of the present study is to investigate the possible role of PI3K/Akt activation on renal Klotho levels during renal compensatory hypertrophy.

Method: We generated a mice model of kidney compensatory hypertrophy (UNX mice) in which kidney klotho levels and circulating mineral metabolism parameters were analyzed. Furthermore, some of the mice were treated with inhibitors of the PI3K/Akt/mTOR pathway. In vitro, proximal tubular epithelial human cells (PTEC) were stimulated with IGF-1 in order to activate the PI3K/Akt pathway, and the effects on Klotho expression were determined.

Results: UNX mice present with an activation of the PI3K/Akt/mTOR pathway in kidney, which correlates with the loss on renal Klotho expression. Moreover, UNX mice showed an increase on both, plasma phosphate and FGF23, and a decrease in the fractional excretion of phosphate (% FEPi). Renal function, estimated by BUN plasma levels, was unaltered. Pharmacological inhibition of the pathway restored Klotho and decreased FGF23 levels, normalizing renal phosphate excretion and blood levels. In vitro, IGF-1 stimulated PI3K/Akt activation in PTEC and induced a decline on Klotho expression, which was restored with PI3K/Akt inhibitors.

Conclusion: The overactivation of PI3K/Akt/mTOR pathway in renal hypertrophy modulates Klotho expression and has direct effects on FGF23 and phosphate. Our findings constitute an important breakthrough in the research of new therapeutic targets in order to maintain renal Klotho levels, and it may be useful in the treatment of kidney disease patients.

RENAAL TUBULAR TOXICITY OF ORGANOPHOSPHATE FLAME RETARDANTS IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Kai-Fan Tsai1, Wen-Chin Lee4, Chien-Te Lee1 and Chia-Te Kung2

1 Kaohsiung Chang Gung Memorial Hospital and Chang Gung University College of Medicine, Kaohsiung, Taiwan, Division of Nephrology,
Department of Internal Medicine, Kaohsiung, Taiwan, Rep. of China and
2 Kaohsiung Chang Gung Memorial Hospital and Chang Gung University College of Medicine, Kaohsiung, Taiwan, Department of Emergency Medicine, Kaohsiung, Taiwan, Rep. of China

Background and Aims: Organophosphate flame retardants (OPFRs) are widely utilized flame retardants and considered less harmful than legacy brominated flame retardants. However, owing to their widespread utilization, OPFRs have led to extensive and persistent human exposure, with potentially hazardous effects on human health such as nephrotoxicity. Experimental and clinical studies have revealed that OPFR exposure is associated with renal tubular toxicity and renal impairment. However, the nephrotoxic mechanisms of OPFRs have not yet been clarified, and their impact on renal tubular injury has less been evaluated in patients with chronic kidney disease (CKD).

In this cross-sectional observational study, we assessed the urinary OPFR concentrations in CKD patients to evaluate the associations between OPFR exposure and renal tubular injury in this population.

Method: Adult CKD patients in Taiwan (≥ 20 years of age and with nondialysis-dependent CKD stage 3–5) were recruited from the Kaohsiung Chang Gung Memorial Hospital between January 2020 and May 2021. The first-void urine samples in the morning were collected to measure the concentrations of 10 common OPFR compounds using an ultra-performance liquid chromatography-tandem mass spectrometry (Waters, Milford, MA, USA). The urinary novel renal biomarkers were also measured using enzyme-linked immunosorbent assays (kidney injury molecule-1 [KIM1] and 8-hydroxy-2-deoxyguanosine [8-OHdG]; Abcam, Trumpington, Cambridge, UK). OPFRs with concentrations below a limit of quantitation (LOQ) were considered undetectable, and LOQ/√2 was assigned to the non-detected samples for analysis. The associations between urinary renal biomarkers and urinary OPFR concentrations (i.e., the sum of 10 OPFR compounds) were assessed via Spearman’s correlation analysis. Simple linear regression analyses were conducted to evaluate the correlations between urinary renal biomarkers, urinary OPFR concentrations, and baseline patient characteristics. The effects of OPFR exposure on the urinary concentrations of KIM1 and 8-OHdG in the enrolled CKD patients were examined in multiple linear regression analyses, adjusting for age, sex, body mass index, diabetes, hypertension, renal function, proteinuria, and covariates with a p-value < 0.1 in univariate analyses via the enter method.

Results: In this study, 163 CKD patients were enrolled for analysis (stage 3: n = 79 [49.47%]; stage 4: n = 48 [29.45%]; stage 5: n = 36 [22.08%]). The overall detection frequency of urinary OPFRs was 98.77% in the study cohort, with a median SOFR of 2.04 μg/g Cr (interquartile range [IQR], 0.84–4.27). The median urinary KIM1- and 8-OHdG concentrations were 185.89 ng/g Cr (IQR, 83.05–441.60) and 71.23 μg/g Cr (IQR, 37.87–149.73), respectively. In our analysis, urinary OPFR concentrations were positively correlated with urinary KIM1 and 8-OHdG concentrations (r = 0.267 for KIM1, p = 0.001; r = 0.281 for 8-OHdG, p < 0.001) (Figure 1). In the multiple linear regression analyses, urinary OPFR concentration was identified as an independent predictor positively associated with urinary renal biomarkers in the enrolled patients, with a 0.260 log ng/g Cr (95% confidence interval [CI], 0.140–0.380, p < 0.001) increase in urinary KIM1 and a 0.227 log μg/g Cr elevation (95% CI, 0.124–0.330, p < 0.001) in urinary 8-OHdG by per log μg/g Cr urinary OPFR (Figure 2).

Conclusion: OPFR exposure is common and associated with renal tubular injury as well as increased oxidative stress in CKD patients, which highlights its nephrotoxic potential in this vulnerable population.
Background and Aims: Through metabolomics research, it was found that in mice with chronic kidney disease, the distribution of lipids in the kidneys was different from that of healthy individuals, and medium-chain fatty acids were reduced. In order to explore the role of medium-chain fatty acids in kidney metabolism and disease, we conducted this systematic review.

Method: Systematic review. The pubmed database was used to search for keywords such as medium chain fat acids, medium chain triglyceride, MCFRA, MCT, chronic kidney disease, CKD, and renal fibrosis.

Results: In chronic kidney disease, long-chain fatty acids decrease and medium-chain fatty acids increase. The increase of medium-chain fatty acids may be a compensatory mechanism. Compared with long-chain fatty acids, medium-chain fatty acids are more easily metabolized through the tricarboxylic acid cycle, thus providing more energy. MCFAs are readily absorbed and transported across the intestinal barrier, with less interference from dietary factors. MCFAs can be rapidly metabolized to provide energy and can also be converted into ketone bodies, which can be used as an alternative energy source in cases of glucose deprivation.

Abstract

THE ROLE OF MEDIUM-CHAIN FATTY ACIDS IN RENAL METABOLISM AND DISEASES

Wu Yiting

Chengdu, P.R. China

Background and Aims: Through metabolomics research, it was found that in mice with chronic kidney disease, the distribution of lipids in the kidneys was different from that of healthy individuals, and medium-chain fatty acids were reduced. In order to explore the role of medium-chain fatty acids in kidney metabolism and disease, we conducted this systematic review.

Method: Systematic review. The pubmed database was used to search for keywords such as medium chain fat acids, medium chain triglyceride, MCFRA, MCT, chronic kidney disease, CKD, and renal fibrosis.

Results: In chronic kidney disease, long-chain fatty acids decrease and medium-chain fatty acids increase. The increase of medium-chain fatty acids may be a compensatory mechanism. Compared with long-chain fatty acids, medium-chain fatty acids are more easily metabolized through the tricarboxylic acid cycle, thus providing more energy. MCFAs are readily absorbed and transported across the intestinal barrier, with less interference from dietary factors. MCFAs can be rapidly metabolized to provide energy and can also be converted into ketone bodies, which can be used as an alternative energy source in cases of glucose deprivation.
oxidized by cells, including cardiomyocytes, and provide a very efficient source of energy production. MCFAs display metabolic, biological, and physical properties that are distinct from LCFA, which may contribute to their reported benefits on the kidney's energy status and function. Only few deleterious effects have been reported with the use of MCFAs, many of which have been reported mainly when MCTs were administered as the main dietary energy source representing 50% of the total energy intake. These include decreased absorption of LCFA, which may result in deficiency in essential polyunsaturated LCFA, steatorrhea, gastrointestinal discomfort, increased risk of ketogenesis and acidosis, and in some studies, though not all, changes in blood lipid profile such as a raise in triglycerides or non-high-density lipoprotein cholesterol.

Conclusion: Studies in animal models indicate that MCFAs may favourably modulate kidney disease progression. Medium-chain fatty acids have protective effects on the kidney and provide new ideas for the relief and treatment of chronic kidney disease.

FGF-23 IN CHRONIC KIDNEY DISEASE: CORRELATION WITH BONE AND CARDIOVASCULAR PARAMETERS – A PRELIMINARY STUDY

Lina Maria Leon Machado 1,2, Gloria del Peso Gilsanz 1,2, María González Casaus 3, Marta Osorio 1,2, Yaniele Hernandez Perdomo 1, Carolina Tornero Marín 1, Pilar Aguado Acín 1, Mónica Coronado Poggio 1, Luisa Fernanda Giraldo 1, Teresa López Fernández 1, María Auxiliadora Bajo Rubio 1,2

Background and Aims: The FGF-23/Klotho ratio increases from early stages of chronic kidney disease (CKD) in parallel with kidney function decline. In some cases, serum FGF-23 levels increase is unbalanced, causing organ damage and increasing cardiovascular risk. The aim of our study was to evaluate the intact FGF-23 (iFGF-23) levels in a cohort of CKD patients and to establish its correlation with cardiovascular and bone mineral metabolism parameters.

Method: A prospective observational study in 59 adult normophosphatemic patients with CKD stage 2-4, was performed. Clinical and analytical variables (serum calcium, phosphorus, intact parathyroid hormone (iPTH), iFGF-23, calcidiol and calcitriol) were evaluated. Basal transthoracic echocardiogram, bone densitometry (Lunar prodigy, GE iDXA), software trabecular bone score (TBS), iNightingal clinical data analyzer and carotid Doppler ultrasound were performed. We excluded patients with background of primary hyperparathyroidism, hepatorenal polycystic disease, kidney transplant, tumoral nephrectomy, active neoplasm, tubulopathies or treatment with active vitamin D or calcimimetics. For statistical analysis, we use SPSS software (T Student, Pearson correlation with cardiovascular and bone mineral metabolism parameters.

Conclusion: Studies in animal models indicate that MCFAs may favourably modulate kidney disease progression. Medium-chain fatty acids have protective effects on the kidney and provide new ideas for the relief and treatment of chronic kidney disease.

DIFFERENCES IN PROTOCOLS FOR MEASURING GLOMERULAR FILTRATION RATE USING IOHEXOL

Marco van Londen1, Arend Bökenkamp2, Etienne Cavalier3, Pierre Delanaye4,5, Natalie Ebert6

1University Medical Center Groningen, Department of Internal Medicine, Division of Nephrology, Groningen, Netherlands, 2Amsterdam University Medical Centers, Department of Pediatric Nephrology, Emma Children’s Hospital, Amsterdam, Netherlands, 3CHU de Liège, Department of Clinical Chemistry, Liège, Belgium, 4CHU Sart Tilman, Department of Nephrology-Dialysis-Transplantation, Liège, Belgium, 5Hôpital Universitaire Carémeau, Service de Néphrologie-Dialyse-Aphérèse, Nîmes, France and 6Institute of Public Health, Charité-Universitätsmedizin Berlin, Berlin, Germany

Background and Aims: When assessing kidney function, measurement of glomerular filtration rate (mGFR) using an exogenous marker such as iohexol is the gold standard. In this study, we aim to identify similarities and differences between iohexol-based mGFR protocols.

Method: Detailed data on iohexol measurement protocols were obtained using a standardized survey sent to centres in Europe and the US. It was completed by 15 participants. Data are reported as number and percentage (n, %).

Results: In the participating centres, measurements are performed after referral by a nephrologist (n=6, 40%), other specialties (n=5, 33%) or for research purposes (n=4, 27%). Most common indications for mGFR are evaluation of kidney donors (n=5, 33%), drug dosing (n=4, 27%), abnormal body composition (n=3, 20%) and transplant evaluation (n=4, 27%). Most participants perform measurements in the morning (n=10, 67%), with patients withholding caffeine (n=5, 33%), fasting (n=4, 27%) or avoiding heavy meals (n=3, 20%). Most centres use an IV iohexol dose of 5 mL 300 mg I/mL (n=10, 67 %) or a dose based on weight (n=2, 13%). The timing of sample collection is shown in Figure 1, most often a single sample per time point (n=12, 80%). Iohexol is measured by LC-MS (n=8, 53%) or LC-UV (n=7, 47%). Within-assay variability ranges between <2% (n=3, 20%) and 6-8% (n=1, 7%) and the between-assay variability ranges between <2% (n=2, 13%) and 6-8% (n=2, 13%). When asked about assumptions and corrections, most centres make a one-compartment assumption in their PK model (n=8, 53%), others making two-compartment (n=2, 13%) or measurement-dependent (n=1, 7%) assumptions. mGFR is standardized for body surface area according to the DuBois-formula (n=6 (40%), Haycock and Schwarz formula (n=2, 13%) or not-specified (n=7, 47%). Some participants correct their measurements for eGFR (n=9, 60 %). Most centres participate in external quality control (Equalis, n=12, 80%).

Figure 1: Timing of samples after iohexol administration. Samples are drawn within the first hour (n=3, 20%), between 1-2 hours (n=13, 87%), 2-3 hours (n=8, 53%), 3-4 hours (n=11, 73%), 4-5 hours (n=9, 60%) or 5-7 hours (n=3, 20%) after iohexol administration.
Conclusion: There is a large variation in protocols for iohexol-based mGFR, which highlights the need for a standardized mGFR protocol before widespread use in clinical routine.

PROGNOSTIC ROLE OF THE NEUTROPHIL-TO-LYMPHOCYTE RATIO IN PATIENTS WITH CHRONIC KIDNEY DISEASE
Eun Hui Bae1, Jin Kim1, Su In Kim1, Da Hae Cho1, Sang Yoeb Lim2, Seong Kwon MA1, Soo Wan Kim1 and Hong Sang Choi1
1Gwangju, Rep. of South Korea and 2Ansan, Rep. of South Korea

Background and Aims: The neutrophil-to-lymphocyte ratio (NLR) has been demonstrated to have prognostic value in cardiovascular disease, infection, inflammatory disease, and several types of cancer. Therefore, it is expected that NLR has predictive value in patients with chronic kidney disease (CKD) but it has not been validated. Here, I aimed to investigate the possibility of NLR as a predictor of progression of CKD.

Method: This retrospective observational study included 141 patients with non-dialysis CKD. Subjects were divided into terciles (T1, T2, and T3) according to NLR. The primary outcome of interest was defined as a composite renal event, which included a decline in the estimated glomerular filtration rate (eGFR) of at least 50% or onset of end-stage renal disease (ESRD) during the follow-up period.

Results: The median follow-up duration was 5.45 ± 2.11 years. The median NLR for each group was 1.35 ± 0.05 in T1 (n=47), 2.16 ± 0.04 in T2 (n=47) and 4.29 ± 0.73 in T3 (n=47). The group with the highest NLR (T3) had higher baseline CKD and serum creatinine and lower eGFR levels than the group with the lowest NLR (T1). The cumulative incidence of composite renal events was significantly increased in T3, compared to T1 (p < 0.001, log-rank test). Cox regression analysis revealed that high NLR was independently associated with the risk of composite renal events (adjusted hazard ratio 2.85, 95% confidence interval 1.18-6.93).

Conclusion: A higher NLR reflects the more advanced stage of CKD and suggests that a role for NLR as a biomarker for predicting CKD progression.

Figure 2B: Kaplan-Meier survival curve for cumulative incidence of decline of kidney function by Neutrophil-to-Lymphocyte ratio.

Figure 2C: Kaplan-Meier survival curve for cumulative incidence of initiation of RRT by Neutrophil-to-Lymphocyte ratio.

Figure 3: Kaplan-Meier survival curve for cumulative incidence of all-cause death by Neutrophil-to-Lymphocyte ratio.
Background and Aims: Increased urinary sodium-to-potassium (Na/K) ratio has been associated with chronic kidney disease. However, we demonstrated that urinary Na/K ratio does not accurately reflect dietary Na/K ratio. Rhythmic patterns of sodium storage and release from the skin interstitium are associated with aldosterone and cortisol levels and previous studies linked tissue sodium accumulation to water conservation. Therefore, we investigated whether the discrepancy between urinary and dietary Na/K ratio could be explained by these factors.

Method: For this post-hoc analysis, we used data from the long-term sodium balance studies Mars105 and Mars520. These studies collected 24-hour urine samples and controlled dietary salt intake for 105 (4 men) and 205 days (6 men) at levels of 6, 9 and 12 grams per day. We calculated the difference between urinary and dietary Na/K ratio. We tested whether this difference varied across salt intake levels in a linear mixed-effects model. Furthermore, we fitted two linear mixed-effect models to explain discrepancies between urinary and dietary Na/K ratio. In the first model, sodium intake, potassium intake, urinary aldosterone and urinary cortisol were fixed effects and each factor random slopes per participant were allowed. In the second model, sodium intake, potassium intake, urinary aldosterone and urinary cortisol were fixed effects and for each factor and dietary Na/K ratio. Furthermore, we investigated whether the discrepancy between urinary and dietary Na/K ratio could be explained by sodium intake, aldosterone, cortisol and urine volume. This suggests that tissue sodium accumulation contributes to the inaccuracy of a single 24-hour urine collection for estimation of dietary sodium and potassium intake.

Results: The median difference between 24-hour urinary and dietary Na/K ratio was −0.08 (IQR: −0.47 to 0.09). At higher salt intake levels the underestimation was significantly larger (mean difference −0.11, −0.22 and −0.36 for 6, 9 and 12 grams salt intake, respectively; P < 0.001). At each salt intake level, higher urinary aldosterone was associated with underestimation of the dietary Na/K ratio (Figure 1A). In contrast, higher urinary cortisol and higher urine volume were associated with relative overestimation of the dietary Na/K ratio (Figure 1B and C, respectively).

Conclusion: The discrepancy between dietary and urinary Na/K ratio can be explained by sodium intake, aldosterone, cortisol and urine volume. This suggests that tissue sodium accumulation contributes to the inaccuracy of a single 24-hour urine collection for estimation of dietary sodium and potassium intake.

FEELINGS OF SAFETY AND SOCIAL BEHAVIOURS AFTER COVID-19 VACCINATION IN PEOPLE LIVING WITH KIDNEY DISEASE AND THEIR SIGNIFICANT OTHERS

Gurneet K Sohanahoa1,2, Naeema A Patel1,2, Ella Ford1,2, Thomas Wilkinson1,3, Courtney J Lightfoot1,2, Alice Smith1,2
1Leicester Kidney Lifestyle Team, Department of Population Health Sciences, University of Leicester, Leicester, United Kingdom, 2Leicester NIHR Biomedical Research Centre, Leicester, United Kingdom and 3NIHR Applied Research Collaboration East Midlands, Leicester Diabetes Centre, Leicester, United Kingdom

Background and Aims: Throughout the majority of 2020, the COVID-19 pandemic forced the UK population, and especially clinically vulnerable people such as those with chronic kidney disease (CKD), to isolate and cease their usual activities outside the home. The COVID-19 vaccine became available in early 2021, with the aim of protecting against COVID-19 infection, reducing the risk of serious illness or death, and consequently allowing a return to more normal social behaviours. In May 2021 we conducted a survey to explore perceptions of increased COVID-19 safety and resultant changes in social mixing behaviour in people with non-CKD CKD (ND-CKD), kidney transplant recipients (KTRs), and their significant others (SOs) after receiving the COVID-19 vaccination.

Method: ND-CKD, KTR and SO participants from 11 hospital sites across England were invited to complete an online survey in May 2021. The survey included items asking about changes to their feelings of COVID-19 risk and safety, and their social behaviours after receiving the COVID-19 vaccine. Participants ranked questions on 7-point Likert scales (perceived COVID-19 safety, 1: feel not safe at all to 7: feel completely safe; changes in social behaviour, 1: no change to 7: complete change), and provided free-text explanations for their ranked responses. Question ratings were analysed by ANOVA, and free-text responses by content analysis to identify common themes.

Results: A total of 59 elder men and 34 females (>65 years) of age with estimated glomerular filtration rate (eGFR) ≥45mL/min/1.73 m² followed up in renal clinics. They were looked for progression to ESRD and morbidity and mortality over time. The age, basic disease, systolic blood pressure, underlying heart disease and stroke was admitted to Nephrology for severe renal failure (P = 0.001), the degree of proteinuria among men was found to be statistically significant as compared to women in this cohort. During a median follow-up of 2.9 years, (22.3% men) developed ESRD while 7.2 % died. The adjusted risks for ESKD and mortality were higher in men as compared to the women in this cohort.

Conclusion: Elderly men have a steeper decline in eGFR along with higher proteinuria as compared to women indicating that the decline in the mean GFR in women was slower than in men, independent of health status.

1Ram Manohar Lohia Institute of Medical Sciences, General Surgery, Lucknow, India, 2Sanjay Gandhi Post Graduate Insitute of Medical Sciences, Department of Nephrology, Lucknow, India and 3Ram Manohar Lohia Institute of Medical Sciences, Department of Medicine, Lucknow, India

Background and Aims: Men with chronic kidney disease (CKD) progress to end-stage CKD at a faster rate than women Data for the association of sex with chronic kidney disease (CKD) progression are conflicting, a relationship between the two especially among elderly population needs understanding.

Method: We conducted a prospective study among all elderly population with CKD attending Nephrology OPD between between Jan 2019-Jan 2022 in Tertiary care hospital, Lucknow and assessed for the stage of CKD and their fall in eGFR over the period of fall in eGFR within a year’s time.

Results: A total of 59 elder men and 34 females (>65 years) of age with estimated glomerular filtration rate (eGFR) <60mL/min/1.73 m² followed up in renal clinics. They were looked for progression to ESRD and morbidity and mortality over time.

Conclusion: Elderly men have a steeper decline in eGFR along with higher proteinuria as compared to women indicating that the decline in the mean GFR in women was slower than in men, independent of health status.

#6475
AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE WITH COMPLETE SITUS INVERSUS: A CASE REPORT

Sanda Mrabet, Dahmane Rihem, Sidina Emah, Raja Boukadida, Awaft Azzabi, Yosra Guedri, Sahhtout Wissal and Dorsalf Zellama
Sahloul Hospital, Nephrology Department, Sousse, Tunisia

Background and Aims: Association between complete Situs inversus and autosomal polycystic kidney disease is rare. The Medline search revealed only three such cases. We report the fourth one. Recent studies have revealed ciliary dysfunction as a cause of both conditions.

Method: We report a case of association of familial hereditary polycystic kidney disease with a situs inversus.

Results: A 52-year-old patient with a familial history of polycystic kidney disease and stroke was admitted to Nephrology for severe renal failure with hypertension. On examination, the patient had a blood pressure of 160/100mmHg. The abdomen was soft, with bilateral palpable renal masses persist in today's environment and highlight the need for communication of high-quality research evidence to encourage uptake of booster COVID-19 and flu vaccines, and effective public education campaigns, to allow clinically vulnerable people to confidently return to pre-pandemic social activity.
with irregular surfaces. Neurological examination was without abnormalities. The most affected creatininemia at 82μmol/L, urea at 44mmol/L, correct ionogram, CO2 at 19 mmol/L, calcium at 1.98mmol/L and uric acid at 860 μmol/L. The 24-hour proteinuria was 1.5g. The cytobacteriological examination of the urine was negative. The chest X-ray showed a situs inversus of the heart. On abdominal ultrasound, the kidneys were polycystic, the liver was seen on left and the spleen on the right. The patient was put on antihypertensive treatment with a calcium channel blocker and Purinol. Given the new and biological improvement, the patient was discharged without monitoring at the outpatient clinic with possible preparation for hemodialysis. In addition, a cerebral MRI angiography was requested to detect cerebral damage because of the family history of stroke.

Conclusion: Polycystic kidney disease is caused by mutations in the polycystic kidney and hepatic disease (PKHD1) gene. Several proteins that are encoded by genes associated with polycystic kidney disease have been identified in primary cilia in renal tubular epithelia. These findings have suggested that abnormalities in cilia formation and function may play a role in the pathogenesis of PKD. Treatment options for PKD are still being explored but further research can develop solutions to increase the life expectancy of patients diagnosed with PKD. Cases like this are rare but could provide more information on the causes of PKD and Situs Inversus leading to these new developments.

#6672
THE DEVELOPMENT OF A COMMUNITY-Nephrology, MULTI-DISCIPLINARY SERVICE
Huda Mahmoud1, Majeed Khan2, Donna Davies2, Lindsay Power2, Emma Ozdemir2, Donna Roberts2, Matthew Dodd2 and Simon Harlin2
1Walsall Manor Hospital, Nephrology Department, Walsall, United Kingdom and 2Walsall Together, Community Services, Walsall, United Kingdom

Background and Aims: The Walsall Together clinical and operational leads constructed a collaborative initiative between nephrology and community services. Driven to provide multi-agency, patient-focused care. The aim of the community nephrology MDT service is to identify and optimally manage individuals with acute nephrological presentations and optimally manage individuals with secondary complications of chronic kidney disease (CKD) at home, while maximally utilising outpatient community services to prevent hospital admissions.

Method: Nephrology and community teams, including rapid-response, complex-case management, enhanced-care and frailty teams devised a MDT service for individuals with either community-acquired acute kidney injury (AKI) or complications of CKD. The MDT service can consist of, a nephrologist, community-CKD nurse, a member from each of the above teams, a community pharmacist and an MDT coordinator. Patients are identified from the MDT attendee’s caseload, from the community heart failure and the community geriatrician patient cohort. A weekly MDT meeting is held on Microsoft Teams, this allows for efficient working across a large geographical area. The MDT coordinator is essential for the efficient performance of the community nephrology MDT. They are responsible for: organising meetings, producing minutes, requesting laboratory investigations (including urine album in creatinine ratio), chasing results from clinical investigations and finally ensuring that the actions generated from the MDT are completed. The community pharmacist is an independent prescriber and immediately actions any medication changes. The community teams consist of advanced clinical practitioners or band 7 above nurse prescribers. All clinical staff perform home visits and fully utilise outpatient services including ambulatory-care unit services for medical assessment, urgent imaging and intravenous electrolyte replacement. The medical-day-case unit services for the administration of blood transfusions. The community outpatient access team services for intravenous iron therapy and antibiotic therapy.

Results: Currently, the community nephrology MDT is actively managing over 60 patients. This excludes patients who have been successfully managed and discharged from the community MDT service. The multimorbid, patient cohort with recurrent hospital admissions appear to have benefited the most. A reduction and/or cessation is noted, in hospital admissions after the introduction of interventions from the community nephrology MDT. The service works with secondary care teams to establish the community MDT service in the community and manage individuals with CKD. This reduces the number of admissions related to secondary complications of CKD. Furthermore, by managing acute illness in the community, the service reduces the number of individuals admitted to hospital with community acquired AKI. Finally, in the unfortunate event of terminal, irreversible pathology, the MDT service allows for advanced care planning and referral to community palliative care services.

Conclusion: The Walsall Together collaboration has demonstrated that utilising a multi-agency approach to managing acute and chronic renal disease, can result in a reduction in hospital admissions. Furthermore, the cooperative multi-speciality approach, has led to improved monitoring and management of housebound individuals with CKD.

#2708
THE EFFECT OF PERCEIVED TEMPERATURE ON THE MORTALITY IN CHRONIC KIDNEY DISEASE PATIENTS
Chun Soo Lim1,2, Jeonghwan Lee1,3, Jung Pyo Lee1,3
1Seoul National University Boramae Medical Center, Department of Internal Medicine, Seoul, Rep. of South Korea and 2Seoul National University College of Medicine, Department of Internal Medicine, Seoul, Rep. of South Korea

Background and Aims: With the global warming, the interest in health risks from the high temperature exposure is growing. The perceived temperature is an equivalent temperature based on a complete heat budget model of the human body. We aimed to analyse the effect of perceived temperature on the overall mortality among patients with chronic kidney disease.

Method: A total of 32,870 patients with chronic kidney disease living in Seoul metropolitan region were recruited in a retrospective cohort (2001-2018). The perceived temperature during summer season (from July to September, at each year) was calculated using various climate factors including air temperature nearby automated weather station, dew point temperature, wind velocity, height of anemometer above ground, and total cloud amount. We assessed the association of perceived temperature using inverse distance weighting on mortality in patients with chronic kidney disease in the Cox proportional hazard model that was adjusted for sex, age, body mass index, estimated glomerular filtration rate, hypertension, and diabetes mellitus status.

Results: During the 6.14±3.96 years, 3,863 deaths (13%) were observed. We confirmed the significant effects of perceived temperature (average perceived temperature: hazard ratio [HR] 1.21, 95% confidence interval [CI] 1.18-1.23; minimum perceived temperature: HR 1.02, 95% CI 1.00-1.05; maximum perceived temperature: 1.20, 95% CI 1.18-1.22) on mortality among patients with chronic kidney disease in univariable analysis. In multivariable analysis, average perceived temperature (HR 1.22, 95% CI 1.19-1.25) and maximum perceived temperature (HR 1.20, 95% CI 1.17-1.23) showed increased risk for overall mortality among patients with chronic kidney disease.

Conclusion: Long-term exposure to high perceived temperature during summer season increased the risk of mortality among patients with chronic kidney disease.

#3880
REDUCED EGFR IS ASSOCIATED WITH IMPROVED SURVIVAL IN PATIENTS WITH RENAL CANCER WHO RECEIVED TARGETED SYSTEMIC ANTI-CANCER THERAPY
Benjamin Elyan1, Rob Jones3, Ninian Lang1, Patrick Mark1 and Jennifer Lees1
1School of Cardiovascular and Metabolic Health, College of Medical and Veterinary Life Sciences, University of Glasgow, Glasgow, United Kingdom and 2School of Cancer Sciences, College of Medical and Veterinary Life Sciences, University of Glasgow, Glasgow, United Kingdom

Background and Aims: Treatment with vascular endothelial growth factor signalling pathway inhibitors (VSP1) and immune checkpoint inhibitors (ICI) has transformed outcomes in advanced renal cancer. A significant proportion of people with renal cancer have co-existing chronic kidney disease (CKD) and concerns persist about the usage of these agents in patients with CKD. We sought to analyse the effect of reduced kidney function on the survival of patients with renal cancer treated with VSI or ICI.

Methods: The Chemocare and NHS West of Scotland SafeHaven databases were linked (data collection spanning 2008–2020), to identify adults from the Greater Glasgow and Clyde Health board who had received either a VSI or ICI as an anti-cancer therapy. We included participants with two available serum creatinine values (at least 3 months apart) before the date of initiation of treatment. The estimated glomerular filtration rate (eGFR) was calculated using CKD-EPI (2009), the average of the two eGFR results (at least 3 months apart) was included in the analyses. Proteinuria was defined as any positive urine albumin: creatinine (>3 mg/mmol) or protein:creatinine (>15 mg/mmol) ratio before treatment. Factors associated with all-cause mortality were analysed using Cox proportional hazards models with R Software.

Results: We identified 349 patients with renal cancer who received at least one cycle of ICI and/or VSI. Sufficient serum creatinine results were available for analysis in 337 of these patients. The average age at first treatment was 63.0 (IQR 55-71) years, 62.5% were male and the median BMI was 28.2kg/m² (IQR 23.9-31.6). Proteinuria results were recorded in 125 patients and 149 patients had nephrectomy prior to treatment. The majority of patients received VSI (88.7%). Over a median follow-up of 335 days (IQR 131 days – 840 days),
281 patients died (Table 1). On univariable analysis, lower baseline eGFR (per 10mL/min/1.73 m² decline in eGFR: HR 0.89, CI 0.84-0.95, p = <0.001) and prior nephrectomy (HR 0.65, CI 0.52-0.83, p = <0.001) were associated with a higher hazards of death. Age (HR 0.99, CI 0.98-1.00, p = 0.245), sex (HR 0.93, CI 0.74-1.18, p = 0.570), BMI (HR 0.99, CI 0.96-1.03, P = .775) and treatment class (HR 0.76, CI 0.51-1.14, p = 0.253) were not associated with higher hazards of death. After adjustment for age, sex and prior nephrectomy, lower eGFR was associated with lower hazards of death (per 10mL/min/1.73 m² decline in eGFR: HR 0.91, CI 0.84-0.97, p = 0.007). In a sensitivity analysis in people who had complete eGFR and proteinuria data available, the presence of proteinuria was associated with greater hazards of death (HR 1.63, CI 1.05-2.12, p = 0.029) after adjustment for age, sex, eGFR and nephrectomy (Figure 1).

Conclusion: Lower baseline eGFR before treatment was associated with reduced hazards of death. This finding was not fully explained by the association of prior nephrectomy with better cancer outcomes. This suggests that other factors may contribute to these discrepancies, such as underlying selection bias of patients for treatment, or bias from the marker used to estimate GFR in this group of patients. The presence of proteinuria was associated with an increased hazards of death and maybe a better marker of renal-associated risk in this group than eGFR and warrants further investigation.

#3859
THE TREND OF RENAL REPLACEMENT THERAPY IN N. MACEDONIA FROM 2015 TO 2020: DATA FROM THE ERA-EDTA ANNUAL REGISTRY

Nikola Gjorgievska¹, Ana Stojanoska¹, Pavlina Dzekova-Vidimliski¹, Dragan Cibrev², Irena Rambabova-Bushijetik¹, Lada Trajcheska¹, Vlatko Karanfiolvski¹, Galina Severova-Andreevska¹, Zhaklina Shterjoova- Markovska¹, Aleksandra Canevskas Taneska¹, Zvezdana Petronijevikj¹, Vladimir Pushevski¹, Petar Dejanov¹, Igor Nikolov¹ and Goce Spasovski¹
¹University Hospital of Nephrology, Skopje, Republic Of North Macedonia and ²University Hospital of Neurology, Skopje, Republic of North Macedonia

Background and Aims: Kidney Failure (KF) is treated with three modalities of renal replacement therapy (RRT): kidney transplantation (Tx), hemodialysis (HD), and peritoneal dialysis (PD). Our study aimed to present the trend of RRT in N. Macedonia from 2015 to 2020.

Method: The epidemiological retrospective study analyzed the patients with kidney failure by gender, age, etiology of kidney disease, and modality of RRT. The data were processed from the annual reports of the European Renal Association-European Dialysis and Transplant Association (ERA-EDTA). The study patients were divided into group 1 (prevalent) with patients on the RRT at the current year, group 2 (incidence at Day 1) with patients on the RRT with a duration of at least 1 day, and group 3 (incidence at Day 91) with patients on the RRT with a duration beyond 91 days.

Results: A total of 10395 patients were analyzed with a mean age of 59.2 ± 9.5 years (median 60.4 years), of which 60.2% were male. From 2015 to 2019, there was an increasing trend in all groups, and most patients were reported in 2019. In group 1, 1598 patients were registered in 2015, and 1762 patients were registered in 2020, which is an increasing trend of 10.3%. The number of patients in group 2 was increasing every following year, with the highest growth
in 2019 up to 12.1%, compared to 2018. The number of patients in group 3 also showed significant growth from 253 patients in 2015 to 324 patients in 2019, but there was a decrease of 16.4% in 2020 (271 patients). Deviations are observed in 2020, with a decrease in the number of patients in group 1 and group 3, as well as a slowdown in the growth dynamics of patients in group 2, which might be associated with the start of the SARS-CoV-2 pandemic. According to the modality, most of the patients (84.7%) were on HD in 2015 and 85.9% in 2020. The most frequent age group of patients was from 45 to 64 years, from 36.3% to 49.4%. There was an increasing trend of patients from older age groups (over 64 years) and male patients. The increasing number of patients from the age group 75+ years was also noted in all groups. Etiology of kidney disease: hypertension (25.8%) and diabetes mellitus (17.4%) were the leading causes of KF in patients requiring RRT.

Conclusion: The study showed a constantly increasing trend of patients with KF requiring RRT. The largest number of patients were men, aged from 45 to 64 years. Hypertension and diabetes mellitus were the leading causes of KF, and most of the patients were treated with HD.

C4 - CO-MORBIDITIES (ANAEMIA, CARDIOVASCULAR, CKD-MBD, ETC.)

#3750
SERUM AMYLOID A AS PROGNOSTIC MARKER FOR CKD AND NON-CKD COVID-19 PATIENTS ADMITTED TO THE EMERGENCY ROOM
Rumen Filev1,2, Mila Cankova1,2, Boris Bogov1,2, Dobrin Svinarov1,3, Juljeta Hristova1,3, Krasimir Kalinov4 and Lionel Rostaing5
1Medical University of Sofia, Internal Disease, Sofia, Bulgaria, 2UMHAT "Saint Anna" Hospital, Nephrology, Sofia, Bulgaria, 3Aleksoandrovska University Hospital, Clinical Laboratory, Sofia, Bulgaria, 4Comac Medical, Sofia, Bulgaria and 5Centre Hospitalier Universitaire de Grenoble, 4 Nephrology, Hemodialysis, Apheresis and Kidney Transplantation Department, La Tronche, France

Background and Aims: Patients with chronic kidney disease (CKD) and a SARS-CoV-2 infection are at higher risk of developing acute kidney injury (AKI) and of mortality after hospital admission. Herein, we assessed whether serum amyloid A (SAA) was associated with outcomes (AKI and/or death). Method: The study group included 160 patients: 70 Covid-19-positive CKD patients (eGFR <60 mL/min), 50 Covid-19-positive patients with no history of kidney disease, 20 Covid-19-negative CKD patients, and 20 healthy controls. We collected data on patients' gender, age, co-morbidities, and laboratory results from blood and urine samples taken at admission into the ER, and from healthy volunteers. All participants gave their informed consent for trial with protocol № 12/31.05.2022 approved by the ethical committee KENIMUS of the Medical University of Sofia, Bulgaria. Laboratory values included calculated eGFR (by the CKD-EPI 2021 formula), highly sensitive inflammatory markers, D-dimer, blood-cell counts, and changes in urine parameters. Co-morbidities included hypertension, obesity, diabetes mellitus, vascular disease, and CKD. All patients had been treated by the official protocol of the Republic of Bulgaria for SARS-CoV-2. We determined the levels of SAA across the four groups to assess if this biomarker could predict AKI, risk of mortality, and if there was a significant difference between the CKD and non-CKD patients.

Results: Overall, median age of Covid-19 patients was 56.4 years; gender ratio was 50% M/F in all groups. Median duration of symptoms before hospitalization was 6 days. Of the 160 patients, 30% were febrile with temperatures >38°C. Overall, creatinine level on admission was elevated in 40% of cases; eGFR was <60 mL/min/1.73 m² in 37.5% of patients. Mean value of eGFR on admission was 82.3 mL/min/1.73 m² for the non-CKD Covid-19-positive group, 49.5 mL/min/1.73 m² for the CKD Covid-19-positive group, 62.3 mL/min/1.73 m² for the CKD patients without COVID-19, and 111.1 mL/min/1.73 m² for the healthy control group. In total, three Covid-19 patients needed renal-replacement therapy: two patients from the CKD group and one...
from the non–CKD group. AKI occurred in 38 Covid-19 patients (23.7%). Of those, 76.3% of the Covid-19 patients with AKI had a serum creatinine level within our cohort of 160 patients, in-hospital mortality was 14.3% (23 patients): of these, 82.6% had AKI (19 patients). Overall, 100% of patients that did not survive Covid-19 also had CKD. We analyzed the levels of SAA across the groups. The reference limits considered for negative results were < 7 pg/mL; the ELISA could measure values up to 300 pg/mL. Of the 23 patients that died, 19 had levels > 300 pg/ml (82.6%), whilst the remainder had results >250 pg/mL. The other patients who survived the infection in our cohort had levels well below 200 pg/ml. When the patients with AKI and without AKI were compared on the basis of SAA, patients with AKI had significantly higher biomarker values (p = 0.02). When compared across the four groups, no significant differences were found except when comparing the healthy control group with the other three groups, where there was significance of p<0.0001 in each comparison.

Conclusion: We confirm that SAA was a reliable biomarker for predicting AKI in Covid-19 patients. It also acted as a predictor for a fatal outcome in patients with severely Covid-19 infection. In conclusion, SAA is a reliable marker, highly informative in the emergency department setting, enabling us to have an early prognosis for the outcome of the Covid-19 infection for the patients in our cohort.

#4399
ALGORITHM-MANAGED DOSING AND PHARMACIST-MANAGED DOSING OF ERYTHROPOIETIN STIMULATING AGENTS IN RENAL ANEMIA: A SYSTEMATIC REVIEW
Francisca van den Oever1, Marijke Dekker2, Erwin Vasbinder1, Teun Van Gelder3 and Patricia Van Den Ben1
1Franciscus Gasthuis & Vlietland, Clinical Pharmacy, Rotterdam, Netherlands, 2Leiden University Medical Center (LUMC), Clinical Pharmacy and Toxicology, Leiden, Netherlands, 3Maasstad Hospital, Nephrology, Rotterdam, Netherlands and 4University Medical Center Groningen, Clinical Pharmacy and Pharmacology, Groningen, Netherlands

Background and Aims: In clinical practice, the treatment of renal anemia is challenging. The attainment of target levels for hemoglobin is often low, due to the high incidence of infections, hyporesponsiveness to erythropoietin stimulating agents (ESA), and suboptimal prescribing of ESA and iron. Several interventions to improve the treatment of renal anemia have been developed, two of them being algorithm-managed dosing and pharmacist-managed dosing of ESA. We performed a systematic review to identify and summarize these two types of interventions and to determine their effectiveness in improving the treatment of renal anemia.

Method: We followed the PRISMA guidelines for systematic reviews. Studies that explored the effect of algorithm-managed and pharmacist-managed dosing of ESA in adult patients with renal anemia were evaluated for inclusion. No restrictions were set on outcome parameters. All observational and interventional studies that included a control group and had a follow-up of at least six months, were eligible for inclusion. Only full-length articles were considered for inclusion. PubMed, Embase, Web of Science, and the Cochrane Library were searched from their inception through July 2022. All included studies were evaluated by two independent reviewers. The quality of studies was assessed by the Newcastle Ottawa Scale and the risk of bias was assessed by the ROBINS-I and RoB1 tools. Data were summarized and tabulated. Studies were grouped according to intervention type, study design, and risk of bias. The protocol of this study was registered in PROSPERO (International Prospective Register of Systematic Reviews) with ID CRD42021243678. This study was funded by the Francisca Gasthuis and Vlietland hospital.

Results: A total of 120 articles were assessed for inclusion, and after screening, 16 articles were included with a total number of 3777 patients. Available evidence was scarce and generally of low to moderate quality; only two RCTs could be identified. All but one of the other studies were observational in nature. The risk of bias was serious in all but one study. Study follow-up was relatively short, varying between six and thirteen months. In six studies, ESA dosing was pharmacist-managed and in one study ESA dosing was algorithm-managed, in nine studies a combination was used. The quality of the intervention description was low to moderate and interventions generally were not reproducible. Although heterogeneity was substantial for outcome parameters, four types of outcome parameters could be determined: hemoglobin/hematocrit, ESA dose and expenditure, iron status, and iron dose. Quantitative synthesis of data was not possible due to the substantial heterogeneity in outcome parameters and the high risk of bias. Therefore, the effectiveness of algorithm-managed and pharmacist-managed dosing of ESA in renal anemia could only be qualitatively assessed for the four types of outcome parameters. In six of the fifteen studies that reported on hemoglobin or hematocrit, the percentage of patients within target levels was significantly higher for the intervention group, whereas in four studies no significant difference was found. Six of the ten studies that reported on ESA dose or ESA expenditure found a significant decrease in ESA dose or expenditure in the intervention group, whereas two studies reported no significant difference. In five of the seven studies that reported on iron status, a significantly higher iron status was found in the intervention group, whereas one non-inferiority study reported no significant difference. In three of the four studies that reported on the iron dose, no significant difference was found between the intervention and the control group, whereas in one study the iron dose was significantly higher in the intervention group.

Conclusion: Available evidence was scarce with a high risk of bias, and quantitative data synthesis was not possible. Therefore, no definite conclusions could be drawn on the effectiveness of algorithm-managed and pharmacist-managed dosing of ESA in renal anemia. Consequently, no recommendations on the implementation of either of the two interventions could be made.

#4405
CHANGES OF VITAMIN D BIOMARKERS ACCORDING TO CAUSE-GLOMERULAR FILTRATION RATE-ALBUMINURIA (CGA) CLASSIFICATION OF CKD PATIENTS
Seunghye Lee1, Jin Hyun Kim1,2, Min-Chul Cho1,2,4, Ha Nee Jang1, Sehyun Jung1, Jung Hwa Jung1,3, Se-Ho Chang1,3,6, Hyejin Jeon1, Hyun-Jung Kim1,3,6
1Gyeongsang National University Hospital, Internal Medicine, Jinju, Rep. of South Korea, 2Gyeongsang National University Hospital, Biomedical Research Institute, Jinju, Rep. of South Korea, 3Gyeongsang National University, Institute of Health Sciences, Jinju, Rep. of South Korea, 4Gyeongsang National University Hospital, Laboratory Medicine, Jinju, Rep. of South Korea, 5Gyeongsang National University, College of Medicine, Laboratory Medicine, Jinju, Rep. of South Korea and 6Gyeongsang National University, College of Medicine, Internal Medicine, Jinju, Rep. of South Korea

Background and Aims: The monitoring of vitamin D status is important to manage metabolic bone disease in patients with chronic kidney disease (CKD). 25(OH)D is used as the vitamin D marker in CKD patients, but vitamin D metabolite ratio (VMR) is also becoming useful as the marker, too. The classification of CKD is based on the cause-glomerular filtration rate (GFR)-albuminuria (CGA) in the KDIGO guidelines. This classification is importantly used in the management decision of CKD and predicts well the prognosis related to CKD. However, there are no study on the changes in various vitamin D markers according to CGA classification. We aimed to investigate the changes of vitamin D biomarkers according to classification by cause of CKD, estimated GFR (eGFR), and proteinuria of CKD patients.

Method: We prospectively analyzed blood and urine samples from a total of 206 patients who received informed consent with CKD class G2-G5. After classifying each group according to the presence or absence of diabetes, eGFR degree, and proteinuria amount, the differences in various vitamin D biomarkers in each group were compared. VMR was the ratio of 24,25(OH)2D to 25(OH)D.

Results: The mean age of the 206 patients was 64.1±12.72 years old. The patients with DM were 46.6% and the most common cause of CKD was glomerular disease (51.4%) including diabetic nephropathy (DN). There was no significant difference in all vitamin D markers we measured in the comparison between the DKD group and the non-DKD group. Among DKD patients, the DN group had significantly lower levels of 25(OH)2D (p=0.012) and bioavailable 25(OH)D (p=0.044) than the no DN group. When divided into three groups according to the degree of eGFR, the mean value of 24,25(OH)2D (p=0.003) and VMR (p<0.001) were significantly lower as the eGFR decreased but all 25(OH)D markers showed no significant decrease with the change in eGFR. In the diabetic patients, when divided into four groups according to the amount of proteinuria, the group with high proteinuria had significantly lower levels of total 25(OH)D (p=0.011), bioavailable 25(OH)2D (p<0.001), free 25(OH)D (p=0.001), and 24,25(OH)2D (p=0.029) compared to the group with low proteinuria but there was no significant difference in VMR. In the non-diabetic patients, when divided into three groups according to the amount of proteinuria, the group with high proteinuria had significantly lower levels of total 25(OH)D (p=0.032), bioavailable 25(OH)D (p=0.010), and free 25(OH)D (p=0.035) compared to the group with low proteinuria but there was no significant difference in 24,25(OH)2D and VMR levels. In these CKD patients, there was no significant difference in the level of VDBP despite the presence or absence of diabetes, the degree of eGFR, and the amount of proteinuria.

Conclusion: As eGFR decreased, the levels of 24,25(OH)2D and VMR significantly decreased. All vitamin D markers we measured showed no significant difference depending on the presence or absence of diabetes except for the low 24,25(OH)2D and bioavailable 25(OH)D levels in DN patients. Regardless of the presence or absence of diabetes, all 25(OH)D
markers decreased significantly as proteinuria increased. Although we showed that significant changes in vitamin D markers differed according to CGA classification, large-scale study and long-term follow-up are necessary for meaningful use in diagnosis and treatment.

#4568
C-REACTIVE PROTEIN / SERUM ALBUMIN RATIO IN PATIENTS WITH COVID-19 AND ADVANCED CHRONIC KIDNEY DISEASE DUE TO TYPE 2 DIABETES MELLITUS

Nataliya Klochkova¹, Mariana Lyansenko¹, Eugene Zeltyn-Abramove¹ and Natalya Belavina²
¹Moscow City Clinical Hospital 52, Pirogov Russian National Research Medical University, Moscow, Russia and ²Moscow City Clinical Hospital 52, Moscow, Russia

Background and Aims: The patients with laboratory confirmed COVID-19 and advanced chronic kidney disease (CKD) due to type 2 diabetes mellitus (T2DM) are at a high risk of adverse outcomes of COVID-19. The mortality in both subgroups was rather high (38.2% vs 38.5% resp.). The median of CPR in (1) was 96 (IQR 27; 144) mg/l (survivors) vs 158 (IQR 43; 193) mg/l (nonsurvivors), \( P = .025 \). The median of SA in (1) was 37.0 (IQR 32.0; 38.5) g/l (survivors) vs 30.0 (IQR 29.6; 33.0) g/l (nonsurvivors), \( P < .001 \). The median of CPR (2) was 69 (IQR 39; 133) mg/l (survivors) vs 90 (IQR 33; 156) mg/l (nonsurvivors), \( P = .246 \). The median of SA in (1) was 34.8 (IQR 32.0; 37.0) g/l (survivors) vs 33.0 (IQR 28.0; 35.0) g/l (nonsurvivors), \( P = .84 \). CPR/SA in (1) subgroup was 2.7 (IQR 0.8; 4.0) (survivors) and 4.9 (IQR 2.6; 5.9) (nonsurvivors), \( P = .012 \). CPR/SA in (2) subgroup was 2.4 (IQR 1.3; 4.3) (survivors) and 2.6 (IQR 1.0; 5.9) (nonsurvivors), \( P = .457 \). Determination of the cut-off point for CPR/SA ratio was based on the receiver operating characteristic (ROC) analysis. Cut off point CPR/SA ratio for (1) subgroup is 3.6 and cut off point for CPR/SA ratio for subgroup (2) is 2.4. 55-days cumulative proportion surviving (Kaplan-Meier method) are presented on the Fig. 1 and Fig. 2. In subgroup (1), a threshold value of the CPR/SA ratio was revealed, which significantly affects the survival of patients. In subgroup (2), it was not possible to identify the threshold value of the CPR/SA ratio, which significantly affects the cumulative survival rate of patients.

Conclusion: CPR/SA ratio >3.6 in patients with advanced DKD not requiring MHD is a laboratory indicator of adverse outcome of COVID-19. The studied parameter did not differ in patients on MHD regardless of the COVID-19 outcomes.

#5868
PREVALENCE AND MANAGEMENT OF CHRONIC COMPLICATIONS IN PATIENTS WITH DIABETES AND ADVANCED CHRONIC KIDNEY DISEASE: A RETROSPECTIVE AUDIT

Cimona D’Souza¹, Acrisa Kakkar¹, Vijayan Suresh¹,², Srikanth Bellary¹,²
¹University of Birmingham, Birmingham, United Kingdom and ²University Hospitals Birmingham, United Kingdom

Background and Aims: Current guidelines recommend that all patients with Chronic Kidney Disease (CKD) stage 3b or higher should be monitored and treated for anaemia, mineral bone disorder (BMD) and metabolic acidosis. We audited the prevalence and management of these complications in a cohort of patients with diabetes and advanced CKD.

Method: A retrospective audit was undertaken using KDIGO guidelines as standard and necessary approvals were secured from the governance team at University Hospitals Birmingham. We included patients with (a) diabetes (b) eGFR 30 and 15 ml/min/1.73 m² and (c) attending diabetes clinics as of 30/09/2022. Using electronic patient records, we collected: demographics, co-morbidities, complications, treatments, body weight, BMI, blood pressure and serial biochemistry (creatinine, Hb,ic, cholesterol, UAab/Creat ratio, bicarbonate, haemoglobin, vitamin D, parathyroid hormone (PTH). Following definitions were applied: anaemia as Hb <13 g/dl for men and <12 g/dl for women, BMD as vitamin D <40 nmol/l plus raised PTH, acidosis as bicarbonate <22 meq/l. Data was analysed using SPSS 26. Descriptive statistics (frequencies and cross tabulations) were used to estimate prevalence. Independent means test was used for continuous variables. Comparison between groups was undertaken using the Chi Square test and one way ANOVA test.

Results: Data for 192 subjects (110 European (EUR), 40 South Asian (SA), 42 African-Caribbean (AFC) /other) was analysed. Mean age (SD) was 73 (±11) years. There were no significant differences in general characteristics between the ethnic groups except for albuminuria which was greater in SA and AFC compared to EUR (193 v 133 v 95.5mg/mmol; \( P = .038 \)). 47% of the cohort had at least one diabetes related complication. 63/192 (32.8%) had cardiovascular disease, 49/192 (25.3%) had retinopathy and 19/192 (9.9%) had neuropathy. Insulin was the most common prescribed glucose lowering agent 105/192 (55%) with proportionately more SA treated with insulin (65%). Anaemia was present in 171/183 (93.4%) of the patients. 82/101 (81.2%) had BMD, and 135/168 (82.8%) of patients had metabolic acidosis. 65/192 (33.9%) of patients had all 3 complications. Only 38/133 (22%) of those with anaemia were receiving treatment out of which only 56.8% were treated adequately with a Hb of >10g/l. Corresponding figures for BMD and metabolic acidosis were: BMD: 39/82 (47.6%) treated and 42% optimally corrected, metabolic acidosis: 54/135 (40%) treated and 53% optimally corrected. There were no significant differences between ethnic groups in prevalence or treatment of these complications.
Table 1: Prevalence and management of CKD-related complications.

<table>
<thead>
<tr>
<th>Complication</th>
<th>Prevalence n (%)</th>
<th>Treated n (%)</th>
<th>Treated and adequately corrected %</th>
</tr>
</thead>
<tbody>
<tr>
<td>Anaemia</td>
<td>171 (93.4)</td>
<td>38 (22.0)</td>
<td>36.8</td>
</tr>
<tr>
<td>BMD</td>
<td>81 (81.2)</td>
<td>39 (47.6)</td>
<td>42.0</td>
</tr>
<tr>
<td>Metabolic acidosis</td>
<td>135 (82.8)</td>
<td>54 (40.0)</td>
<td>53.0</td>
</tr>
</tbody>
</table>

Conclusion: The prevalence of CKD related complications is high. The management of these complications however, is suboptimal. Increased emphasis on the management of these complications is required to improve outcomes in patients with advanced CKD.

#4424
FREQUENCY OF RED BLOOD CELL TRANSFUSION USE IN PATIENTS WITH ANEMIA OF CHRONIC KIDNEY DISEASE (CKD) IN EUROPE: A SYSTEMATIC LITERATURE REVIEW

Jake Hunnicutt1, Anadi Mahajan2, Ravalitha Gajjala2, Saifuddin Kharawala3 and Anna Richards4
1 GSK, Collegeville, PA, United States of America, 2 Bridge Medical Consulting, Richmond, United Kingdom and 3 GSK, Brentford, Middlesex, United Kingdom

Background and Aims: Anemia of CKD is common and managed with oral or intravenous iron, erythropoiesis-stimulating agents (ESAs) and, when necessary, red blood cell transfusions (RBCT). Reducing RBCT use is a goal in the management of anemia of CKD due to known short term (e.g., hyperkalaemia, heart failure) and longer term risks (e.g., allosensitization), but there is limited collated data on their use in Europe. A systematic
literature review was conducted to evaluate the frequency of RBCT use among dialysis and non-dialysis (ND) patients, and associated data reported for predictors of RBCT receipt, complications, healthcare resource use (HCRU), and costs.

Method: A comprehensive search strategy was used to retrieve real-world (RW) studies and randomized controlled trials (RCTs) conducted in DD and ND CKD patients with anemia using Embase and Medline (1980 to June 2022). Searches of conference abstracts, bibliographies and grey literature were also conducted. Studies which included European patients' data are described here.

Results: Of the 3495 citations retrieved, 182 relevant studies were identified including 54 studies with European patients. Thirteen were RW studies including 12 quantifying the frequency of RBCT use (Table). In RW studies, the overall frequency of RBCT use ranged from 4.3–35.0% across studies and for key subgroups (n=10 studies: DD only studies, 8.4–33.9%; ND only studies, 4.3–35.0%). The number of RBCT units per patient-year (PY) ranged from 1.4–2.7 among DD patients (n=2 studies; no ND studies found). RBCT use appeared to vary by patient factors (iron/ESA use, CKD stage), by study design (e.g., length of follow-up) and across countries (but with no clear patterns in geographic variation). For the 41 RCTs including European patients (single country, n=3 studies, multi-country, n=38 studies), the overall frequency of RBCT use ranged from 0–21.6% (DD only studies, 0–21.6%; ND only studies, 0–14.8%), which was lower than those recorded in the RW studies. The rate of RBCT use in trials ranged from 3.5–66.0 events per 100 PY overall (DD only studies, 3.5–66.0; ND only study, 8.0); the number of RBCT units per PY ranged from 0.20–1.65 among DD patients (n=2 studies; no ND studies found). No studies used statistical modelling to quantify predictors of RBCT use while adjusting for potential differences between groups. One RW study from 1986 reported detection of human T-lymphotropic virus type III (HTLV-III; subsequently known as HIV) antibodies in 4 patients who had received RBCT (in a sample of 276 screened chronic HD patients). Of three RW studies reporting data on costs, two were >30 years old and one provided costs relating to receipt of inpatient RBCT in ND patients stratified by oral iron, low dose, or high dose intravenous iron use from 2013–2015 (n=111).

Conclusion: RBCT use forms part of the management of anemia of CKD in Europe and its use is variable but not infrequent. RBCT risk in RW studies appeared elevated compared to RCTs. There were no consistent patterns in geographic variation, but risk varied by patient factors and study design. There is currently limited European data reporting on frequency of associated complications, predictors of RBCT use, associated HCRU and costs. Funding: GSK (Study 211829).

#5963
THE ASSOCIATION OF FRAILTY, DENTAL STATUS, INFLAMMATION AND MALNUTRITION IN HEMODIALYSIS PATIENTS

Tuğçe Topoğlu Çağlar1,2, Yasemin Erten1, Saliba Yıldırım3, Funda Yıldırım Borazan4 and Handan Ozkula5

1 Ankara, Turkey, 2 Gazi University Faculty of Medicine, Department of Internal Medicine, Ankara, Turkey, 3 Gazi University Faculty of Medicine, Nephrology, Ankara, Turkey, 4 Gazi University Faculty of Medicine, Geriatrics, Ankara, Turkey and 5 Gazi University Faculty of Dentistry, Ankara, Turkey

Background and Aims: Persistent low-grade inflammation and malnutrition in chronic kidney disease (CKD) are associated with so many CKD complications. Frailty, the state of increased vulnerability often associated with aging, had a higher incidence in CKD patients regardless of age. In this study, we aimed to investigate the frequency of frailty among hemodialysis patients and volunteers with normal kidney function to define its relationship with inflammatory markers, biochemical parameters and dental status.

Method: A cohort of 86 CKD patients with hemodialysis (HD) and 74 volunteers with normal kidney function (similar in terms of age and gender distribution) were included in this study. Both groups were evaluated by the Clinical Frailty Scale in three groups as non-frile, pre-frail and frail. Demographic characteristics, biochemical parameters and dental status were recorded.

Results: 21 of 86 patients (24.4%) were frail in CKD patients with HD, and 4 of 76 patients (5.4%) in the control group were frail (p<0.001). The frail individuals in the HD group were older (p<0.001), had more systemic diseases (p<0.001), had higher serum C-Reactive Protein (CRP) levels (p<0.001), lower serum albumin levels (P = .001), lower serum creatinine levels (p<0.003). When the number of teeth was evaluated: the number of patients with more than 20 teeth was significantly lower in the frail group than in the non-frail group (p<0.001).

Conclusion: In our study, the frequency of frailty in hemodialysis patients was found to be significantly higher than in the control group. The lower albumin and serum creatinine levels, the higher CRP levels and the lower number of teeth suggest the relationship between frailty with dental status, malnutrition and inflammation in hemodialysis patients. It can be concluded that improvements in oral health and/or inflammation status can contribute to the improvement of frailty in this patient group.

#6754
THE EFFECT OF REDUCED RFN FUNCTION ON SEXUAL FUNCTION IN PATIENTS WITH HEART FAILURE

Charalampos Loutradis1, Konstantinos Koutsampasopoulos1, Eleni Intezividou1, Konstantinos Stavropoulos1, Evangelos Sdogkos2, Konstantinos Imprialis2, Ioannis Vogiatzi2, Christodoulos Papadopoulos1 and Michael Doumas1

1 Hippokration Hospital, Aristotle University of Thessaloniki, 2nd Proxepidetic Department of Internal Medicine, Thessaloniki, Greece, 2 Veria General Hospital, Department of Cardiology, Veria, Greece and 3 Hippokration Hospital, Aristotle University of Thessaloniki, 3rd Department of Cardiology, Thessaloniki, Greece

Background and Aims: Sexual Dysfunction is a common and often undiagnosed complication in patients with Heart Failure (HF) or Chronic Kidney Disease (CKD). Sexual dysfunction presents a strong association with cardiovascular disease and death. This study aims to evaluate the possible effect of reduced renal function on the sexual dysfunction in patients with heart failure.

Method: This is a prospective case-control study in patients with Heart Failure (clinical diagnosis based on relevant symptoms and/or signs) with preserved or reduced renal function, defined as estimated glomerular filtration rate (eGFR) >60 and <60 ml/min/1.73 m², matched for age (± 5 years). The eGFR was calculated with the CKD-EPI equation. Sexual dysfunction was evaluated with the validated Female Sexual Function Index Scoring (FSFI) and the International Index of Erectile Function (IIEF) questionnaires in the native language.

Results: A total of 214 (107 per group) patients were included in this study. Patients’ age 74.10±8.97 vs 75.81±8.66; P = .157), gender (males: 65.4% vs 57.9%; P = .261) and BMI (28.10±4.90 vs 28.99±4.43; P = .164) were not different between the two study groups. In total population, sexual dysfunction was more prevalent in patients with eGFR>60 compared to <60 ml/min/1.73 m² (75.7% vs 88.8%; P = .012). In females, no significant differences were evidenced in sexual dysfunction based on FSFI score <26.0 (91.9% vs 95.6%; P = .490). In contrast, males with preserved renal function had lower prevalence of sexual dysfunction (IIEF<22) compared to those with reduced renal function (67.1% vs 83.9%; P = .027). In regression analysis eGFR was an independent factor associated with sexual dysfunction.

Conclusion: Renal dysfunction may be an important factor predisposing heart failure patients to more frequent sexual dysfunction.

#6794
CALCIUM/MAGNESIUM RATIO IN PATIENTS WITH DIABETES AND CHRONIC KIDNEY DISEASE: A RISK FACTOR FOR CARDIOVASCULAR DISEASE

Henrique Borges, Rita Afonso, Roberto Calças Marques, Teresa Jerónimo and Ana Silva
University Hospital Center of Algarve, Faro, Faro, Portugal

Background and Aims: Chronic Kidney Disease (CKD) and Diabetes Mellitus (DM) are significant risk factors for Cardiovascular (CV) Disease. Patients with CKD and/or DM exhibit higher incidence and prevalence of CV events compared to the general population. Hypomagnesemia and elevated calcium-magnesium (Ca:Mg) ratios have been identified as independent risk factors for CV-related deaths. The aim of this study is to determine the relationship between Ca:Mg and the prognosis of CV disease in patients with CKD and DM.

Method: This cross-sectional study enrolled patients with DM and CKD followed at Diabetic Nephrology appointments in a hospital. The study population was divided into two groups: Group 1 (G1) - patients who had a previous hospitalization due to a CV event, and Group 2 (G2) - patients without CV-related hospitalizations. A logistic regression model was employed to evaluate the predictive factors for CV hospitalization for the variables studied.

Results: A total of 223 patients were included in the study: 92 females and 131 males, with an estimated glomerular filtration rate of 38±42 mL/min/1.73 m² and 41% had been hospitalized due to a CV event. G1 had higher age (P = .02), higher serum phosphate (p = .001), parathormone (p = .01), interleukin-6 (p = .01), FGF-23 (p = .01), oxidized-LDL (p = .01), Ca:Mg (p = .01), and pulse pressure (p = .01), as well as lower eGFR (p = .01) and magnesium
Conclusion: In this population, Ca:Mg and FGF-23 were predictors of CV patients. These parameters may be valuable in clinical practice to identify high-risk morbidity. Further studies are necessary to fully understand the relationship of -0.54 kg was found between FFMBIS and FFMCT (LoA: -14.88 to 13.7 kg, p=0.544). Between LTM_BIS and FFM_CT a mean difference of -12.2 kg was apparent (LoA: -28.7 to 4.2 kg, p<0.001). Compared with FFM_CT, the highest occurrence of accurate predicted protein requirements was found for FFM_BIS. Mean difference between protein requirements according to FFM_BIS and FFM_CT was -0.7 ± 9.9 grams in males and -0.9 ± 10.9 grams in females.

Conclusion: FFM_BIS seems a valid surrogate measure for the estimation of FF as compared to FFM_CT. As expected, large clinically relevant differences were observed in calculated protein requirements when comparing multiple methods, with FFM_BIS having the best accuracy compared to FFM_CT.

#4852
LATE REFERRAL OF PATIENTS WITH AN UNKNOWN CAUSE OF CHRONIC KIDNEY DISEASE AND MALIGNANT HYPERTENSION
Tamar Tevdoradze1, Irma Tchokhonelidze1, Miranda Tsilosani2, Nora Sarishvili1, Tamar Kasradze1, Dalakishvili Ketevan1, Nona Babutsidze1, Gvantsa Metshkharishvili1, Nino Buadze1, Tamar Bagashvili1, Rusudan Rusia1, Giorgi Gazdeliani1, Mariam Beridze1, Ana Tchikaberidze1, Teona Khelasvili1, Ketevan Kapanadze1 and Nani Khidasheli1
1Tbilisi State Medical University/HMT University Clinic, Nephrology, Tbilisi, Georgia and 2V.Iverieli Endocrinology Metabology Dietology Center "ENMEDIC", Pathology, Tbilisi, Georgia

Introduction: Systemic sclerosis (SS) is a rare connective tissue disorder characterized by widespread vascular dysfunction and progressive skin and internal organ fibrosis. Scleroderma renal crisis (SRC) is a life-threatening complication of SS. The estimated incidence of SS is approximately 20 cases per million per year, and SRC affects about 5-15% of these patients.

Case Description: A 32-year-old female was admitted to the hospital with dyspnea, edema, HTN, COPD. 4 months before the hospitalization, she had an abrupt onset of HTN (230/120 mmHg) and seizures (no abnormal waveforms on EEG). Vital signs: HR 90’, RR 22’, BP 197/121 mmHg, SpO2 90% on room air. PEx: severe jugular venous dilation, crackles in both lungs, 3+ pitting edema bilaterally. The skin appeared abnormal with a modified Rodnan score “9” out of “51” with puffy hands, sclerodactyl, telangiectasia, and Raynaud’s phenomena. Lab: creatinine 406 mcmol/L, urea 20.8 mmol/L, T.Ca 2.04 mmol/L, P 1.71 mmol/L, PTH 255.5 pg./mL, Alb 33 g/L, LDH 596 U/L. Urinalysis: UPCR of 4.169 mg/mg creat. microhematuria ANA

Figure 1: Patient’s hands with Raynaud’s phenomena.

Figure 1: Bland-Altman plots of muscle compartment measurements. (A) FFM_BIS versus FFM_CT; (B) FFM_BIS versus FFM_CT in males. (C) FFM_BIS versus FFM_CT in females. Abbreviations: FFM_CT = computed tomography derived fat free mass, FFM_BIS = bio impedance spectroscopy derived weight fat free mass. Differences were calculated by subtracting FFM_CT from FFM_BIS.
Figure 2: Telangiectasias.

Figure 3: Microthrombi in small interlobar arteries.

Figure 4: Intimomedial mucoid degeneration of the vascular wall.
Figure 5: Late changes in small arteries manifested by intimal thickening and proliferation (vascular “onion-skin” appearance).

Figure 6: Ischemic changes in glomeruli.

Figure 7: Acute tubular injury.
were positive for centromere pattern with a titer of >400 AU/mL (N = 40). CENP-B + anti-CCP, ANA, Anti-Jo1 and anti-Sm antibodies. A kidney biopsy showed acute tubular injury in the early stage, and later stages of interstitial fibrosis and tubular atrophy; chronic active thrombotic microangiopathy (TMA), vascular abnormalities including intimal accumulation of myxoid material, thrombosias, fibrinoid necrosis consistent with Scleroderma Renal Crisis (Fig 3; 4; 5; 6; 7) The patient started treatment with losartan 100mg. 3 months she started hemodialysis due to diuretic refractory overhydration with severe pulmonary edema resulting in acute kidney injury hospital readmission.

Discussion: SRC was at one time almost uniformly fatal, with the kidney histopathology workup, neither clinical presentation nor lab tests inevitably leading to irreversible changes resulting in CKD. Notably, until damage to the kidney, presenting with combined nd-SRC and SSc-TMA, eventually leads to microvascular thrombosis. Our case demonstrates severe significant hypertension. The pathology of SSc-TMA shows abnormalities in the capillary wall which eventually leads to microvascular thrombosis. Our case demonstrates severe damage to the kidney, presenting with combined nd-SRC and SSc-TMA, inevitably leading to irreversable changes resulting in CKD. Notably, until the kidney histopathology workup, neither clinical presentation nor lab tests revealed typical TMA. SRC was at one time almost uniformly fatal, with death often occurring within a few weeks. With the development of ACE-I, sur Ethiopians, hyperphosphatemia and hyperkalemia in elderly Koreans. In 12% of cases, both 2% with the Limited cutaneous systemic sclerosis (lcSS) and 12% in the Diffuse cutaneous systemic sclerosis (dcSS). Histopathologically SRC can be divided into narrowly defined nd-SRC and SSc-associated TMA: nd-SRC is a typical type of SRC, which shows acute renal failure and abrupt onset of moderate-to-significant hypertension. The pathology of nd-SRC shows injured endothelial cells and subsequent intimal thickening in the arcuate and interlobar arteries. The pathology of SSc-TMA shows abnormalities in the capillary wall which eventually leads to microvascular thrombosis. Our case demonstrates severe damage to the kidney, presenting with combined nd-SRC and SSc-TMA, inevitably leading to irreversible changes resulting in CKD. Notably, until the kidney histopathology workup, neither clinical presentation nor lab tests revealed typical TMA. SRC was at one time almost uniformly fatal, with death often occurring within a few weeks. With the development of ACE-I, sur

Conclusion: SSc should be considered in any patient presenting with malignancy or AKI. SRC can occur in patients without evidence of skin thickening or other manifestations of SSc. Early diagnosis improves outcome. A kidney biopsy should be gold standard in all patients with “unknown” causes of the CKD. ACEi remains the cornerstone of the treatment. Renal Transplantation: to discuss after two years after start of dialysis.

#4964

ASSOCIATION OF DIETARY INTAKE WITH SERUM LEVELS OF PHOSPHORUS AND POTASSIUM IN THE ELDERLY HEMODIALYSIS PATIENTS IN KOREA

Jung-Hyun Kim¹, Dong-Ryeol Ryu², Hyun-Jung Kim³, Min-Sook Kyung⁴,⁵

1Paichi University, Department of Food and Nutrition, Daejeon, Rep. of South Korea, 2Yonsei JS Clinic, Rep. of South Korea, 3Ewha Womans University, Rep. of South Korea, ⁴Rep. of South Korea and ⁵Daejeon Seogu Children Food Service Management Center, Rep. of South Korea

Background and Aims: Dietary management of elderly (>60 years old) hemodialysis (HD) patients is very important for solving health problems and improving quality of life. Hyperphosphatemia and hyperkalemia in elderly HD patients are closely related to intake of dietary phosphorus and potassium from Koreans’ unique eating patterns. It is very difficult to manage the diet of hemodialysis patients due to the unique eating patterns of elderly Koreans. In the daily meal pattern, sodium and potassium contents are high in grain-based foods, soups, stews, and seasoned vegetables. And, there are various recipes for meals using a range of condiments, which increase serum phosphorus level. For this reason, it is necessary to educate dietary management using real-time Apps for the elderly in Korea. This study was designed to provide the base data for the development of a self-dietary management App for Korean elderly HD patients.

Method: This study was conducted on 237 elderly HD patients (149 males and 88 females) at nationwide 18 university hospitals. We collected anthropometric data, biochemical parameters, and dietary data of the subjects. Dietary data for usual intake were obtained by use of a food-frequency questionnaire (FFQ) consisting of 23 food meal items based on the Korean usual diets. For this dietary status evaluation, a newly constructed potassium and phosphorus content DB was used.

Results: The average age of the patients was 69.7±11.6 years for men and 69.2±6.9 years for women and the duration of HD was 5.4 ± 4.9 years for men and 5.5±4.2 for women. The mean body mass index (BMI) was 23.24 ± 2.99 kg/m², mean serum phosphorus level was 5.03 ± 9.59 mg/dL, and mean serum potassium level was 5.41 ± 8.58 mEq/L. Hyperphosphatemia (> 4.5 mg/dL) was found in 45.8% of the subjects, and hyperkalemia (> 5.0 mEq/L) in 35.4%. Energy and protein intake were significantly lower than recommended intakes of HD patients (P = .027, P = .015). Lower intake of energy and protein was more significant in women. The intake of sodium and potassium was

significantly higher than recommendation (P = .014, P = .021), which was more excessive in men. Serum phosphorus levels showed positive correlation with intake frequency of mixed grains rice (P = .011), noodle without broth (P = .000), vegetable soup (P = .039), and roasted beef (P = .047) in male patients. In case of female patients, intake of sweet potatoes was correlated with hyperphosphatemia (P = .047). Serum potassium levels showed a positive correlation with intake of Kimchi (P = .000), noodle without broth (P = .000), and ham (P = .018) in men. In women, sweet potatoes (P = .027) and medium- sized potato (P = .047) were correlated with serum potassium level. On the other hand, intake of white rice showed negative correlation with serum potassium levels (P = .037) in both sex.

Conclusion: Dietary management along with medical treatment is essential for maintaining serum phosphorus and potassium levels within acceptable ranges because the composition of the daily routine diet is very unique and varies in Korea. The results of this study showed that the intake of white rice rather than mixed grains is an important factor in sustaining normal serum phosphorus and potassium levels in the elderly Korean HD patients. In addition, limiting intake of sweet potatoes, medium and high potassium vegetables & fruits to under three servings per week is recommended. Therefore, customized dietary management needs to be regulated according to each individual’s dietary pattern for the Korean elderly HD patients. Major variables found in this study can be used in the development of new App for customized self-dietary management.

#2538

HEALTHY PLANT-BASED DIET IN CHRONIC KIDNEY DISEASE THROUGH USE OF SODIUM ZIRCONIUM CYCLOSILICATE (HELPFUL TRIAL): LABORATORIAL FINDINGS

Carla Maria Avesani1, Olof Heimbürger1, Torsten Sallstrom2, Awa Danieïsson3, Charlotta Rubin4, Gerd Faxon Irving5, Bengt Lindholm6 and Peter Stenvinkelb7

1Karolinska Institutet, Department of Clinical Science, Technology and Intervention, Stockholm, Sweden, 2Nyköping Hospital, Department of Diabetics, Nyköping, Sweden, 3Karolinska University Hospital, Medical Unit Nephrology, Stockholm, Sweden, 4Karolinska Institutet, Medical Unit Clinical Nutrition, Stockholm, Sweden and 5Karolinska Institutet, Department of Neurobiology, Care Sciences and Society, Stockholm, Sweden

Background and Aims: Patients with chronic kidney disease (CKD) and hyperkalemia (HK) are counselled to follow a diet restricted in potassium (K) which limits the intake of fruits and vegetables. This is a cause of complaints for many patients. The use of the K lowering medication sodium zirconium cyclosilicate (SZC) has the potential to treat HK and allow a healthy plant-based diet (PBD). We designed a clinical trial to explore the safety and feasibility of prescribing a healthy PBD to CKD patients with HK with the concomitant use of SZC.

Method: The HELPFUL trial is an ongoing single-arm study with patients with CKD stage 4-5 on dialysis and with plasma K between 5.1 to 6.5 mmol/L at inclusion. Patients are followed for 6 weeks. In the first 3 weeks, SZC is prescribed to normalize plasma K (pK) while ingesting a low protein diet with low K+ content. In the subsequent 3 weeks, a healthy PBD with a target pK of 3700 mg/day is prescribed maintaining the use of SZC. A food basket with the PBD is delivered to the participants weekly. A weekly monitoring of pK and titration of SZC to keep normokalemia is performed. Other laboratory measurements and food intake are assessed at baseline, week 3 and week 6. Food intake is evaluated using the 24-hour food record (24HFR). Data was analyzed by repeated measures-ANOVA or by Friedman test for related samples, as appropriate. The protocol is registered at www.clinicaltrials.gov (identifier NCT04207203).

Results: 22 patients were included (59±13 years; 13 men, 59%). Table 1 describes the main findings. During the study, eGFR did not change, serum urea decreased, and P-carbon dioxide increased significantly. Inflammatory markers, 24hour urinary sodium and K excretion did not change. Potassium intake from 24h-FR increased, as well as the intake of fruits, vegetables and nuts after the PBD. The mean pK normalized in week 3 and 6. After the start of PBD, 3 patients (13.6%) had pK between 5.1 and 5.3 mmol/L. Most patients needed SZC dose of 10g/day. No changes were observed in dose of RAAS.

Conclusion: The strategy of PBD food basket with concomitant use of SZC allowed an increase in dietary K intake with higher intake of fruits, vegetables and nuts. P-carbon dioxide, a surrogate of bicarbonate improved as well. The pK was kept within normal values for most of the patients.

**SERUM APELIN AND RENAL PROGNOSIS IN PATIENTS WITH NON-DIALYSIS DEPENDENT CHRONIC KIDNEY DISEASE**

Nao Kani1, Michinori Hirata2, Shuzo Makino1, Tomoya Naka1, Kazuhiro Okamoto1, Hiromitsu Miyakawa1, Ryuta Uwatoko1, Sakii Bessho1, Nobuhiro Hashimoto1, Rei Iio1, Yoshiyasu Ueda1 and Terumasa Hayashi1

1Osaka General Medical Center, Kidney Disease and Hypertension, Osaka, Japan and 2Chugai Pharmaceutical Company, Co., Ltd., Tokyo, Japan

**Background and Aims:** The apelin/APJ system is a novel pleiotropic system with an essential role in renal and cardiovascular physiology and disease. A role for the apelin/APJ system in diverse pathological states, including disorders of sodium and water balance, hypertension, heart failure, pre-eclampsia, acute kidney injury, sepsis and diabetic nephropathy, has recently been reported. Especially, the impact of apelin/APJ system on cardiovascular system has been attracting attention, but scarce data is available in chronic kidney disease (CKD).

**Method:** We measured serum apelin-36 by ELISA in 411 outpatients with non-dialysis dependent (NDD) CKD and analyzed factors associated with serum apelin. Furthermore, we examined the association of serum apelin with renal outcome (renal replacement therapy, RRT) using multivariate Cox proportional hazards model.

**Results:** Median age and eGFR were 71 years and 21.7 ml/min/1.73 m², respectively and the prevalence of male gender and diabetes was 26.8% and 50.8%, respectively. Median serum apelin was 0.81 pg/ml. There was no significant difference in serum apelin level between male and female patients, or those with and without diabetes. Moreover, serum apelin level had no significant association with age and eGFR; however, there was a significant relationship between serum apelin and brain natriutetic peptide. During the follow-up period of 38 months, 126 patients started RRT. eGFR and age were associated with the time to RRT induction. Serum apelin was not associated with renal outcome (HR, 1.05; 95%CI, 0.64-1.71; P=0.86); however, this association was interacted by diabetes and gender (P for interaction, 0.073 and 0.070, respectively).

**Conclusion:** Serum apelin could be a predictive marker of renal prognosis in male and non-diabetic CKD patients.

**RELATIONSHIP BETWEEN MONOCYTE-LYMPHOCYTE RATIO AND RENAL OUTCOMES IN PATIENTS WITH TYPE 2 DIABETES**

Yue Gu, Yingying Ren and Jing Zhou

Henan Provincial People’s Hospital; Zhengzhou University People’s Hospital; Henan University People’s Hospital, Department of Nephrology, Henan Provincial Clinical Research Center for Kidney Disease, Henan Provincial Key Laboratory of Kidney Disease and Immunology, Zhengzhou, P.R. China

**Background and Aims:** Acute kidney injury (AKI) is a common complication of hospitalized adults with increased risk of chronic kidney disease and end-stage kidney disease. Sepsis is the most common reason of AKI in patients admitted in intensive care unit (ICU) with the incidence over 50%. Soluble urokinase-type plasminogen activator receptor (suPAR) is an important immune mediator involved in kidney injury. Numerous studies have shown that the suPAR is associated with a variety of kidney diseases. However, it remains unknown on the diagnosis and prognosis value of suPAR in sepsis-associated acute kidney injury (S-AKI). Hence, this study aimed to explore the diagnostic value for the prediction of S-AKI courses and 28-day death.

**Method:** In this prospective study, adult patients with sepsis admitted to the ICU of Henan people’s Hospital from December 2020 to February 2022 were enrolled. Plasma suPAR levels at 0, 12, 24 and 48 hours after admission to ICU were measured by enzyme-linked immunosorbent assay. We assessed the development of S-AKI as the primary outcome and the occurrence of death within 28 days in patients who had S-AKI as a secondary outcome. The prediction of the suPAR level on S-AKI and death was tested using receiver operating characteristic curve (ROC) analysis, by calculating the area under the curve (AUC), and 95% confidence interval (CI).

**Results:** Of the 182 sepsis patients, 66 (36.3%) developed AKI during hospitalization, of whom 31 (46.9%) died. At 12, 24 and 48 hours after admission to ICU, the plasma suPAR level was significantly higher in patients with S-AKI than in patients without AKI (P<0.05). (Fig. 1) In sepsis patients dead with 28 days after admission in ICU, the plasma suPAR level was significantly higher at 0 and 48 hours after admission in ICU compared to the survival patients (P<0.05). (Fig. 1) Diagnostic performance of plasma suPAR level improved over time with the highest area under the receiver operating characteristic curve of 0.701 (95% CI, 0.623–0.779) 24 hours after study inclusion. Additionally, plasma suPAR levels at 0h have the highest area under the receiver operating characteristic curve of 0.647 (95% CI, 0.512–0.782) in predicting 28-day death. The best discrimination ability for the S-AKI was achieved for suPAR 24 hours after inclusion by applying a cutoff value of greater than or equal to 6.31 ng/ml (sensitivity 62.1, specificity 71.6). The suPAR at 0h after inclusion performed best in discriminating 28-day death by using a cutoff value of greater than or equal to 4.57 ng/ml (sensitivity 87.1, specificity 51.4). (Table 1)

**Conclusion:** Plasma suPAR level can be a potential biomarker for early diagnosis of S-AKI and has a certain clinical value in predicting the short-term death of S-AKI. However, further clinical studies with larger sample size is needed.
Figure 1: Comparison of suPAR levels between the S-AKI vs non-AKI groups and the survival vs death groups at 0, 12, 24 and 48 hours after admission to ICU.

CHANGES IN THE CLINICAL CHARACTERISTICS AND MANAGEMENT OF PATIENTS WITH AHUS OVER 10 YEARS: TRENDS FROM THE GLOBAL AHUS REGISTRY

Andrew Siedlecki, Imad Al-Dakkak, Katerina Anokhina, Gema Ariceta, Gianluigi Ardissino, Laurence A. Greenbaum, Christoph Licht and Johan Van de Walle

1Brigham and Women’s Hospital, Department of Internal Medicine, Renal Division, Boston, United States of America, 2Alexion, AstraZeneca Rare Disease, Boston, United States of America, 3Vall d’Hebron Hospital, and the Autonomous University of Barcelona, Department of Pediatric Nephrology, Barcelona, Spain, 4Centro per la Cura e lo Studio della Sindrome Emolitico-Uremica, Fondazione IRCCS Ca’ Granda Ospedale Maggiore Policlinico, Milan, Italy, 5Emory University School of Medicine and Children’s Healthcare of Atlanta, Division of Pediatric Nephrology, Atlanta, United States of America, 6The Hospital for Sick Children, Division of Nephrology, Toronto, Canada and 7Ghent University Hospital, Department of Paediatrics and Medical Genetics, Ghent, Belgium

Background and Aims: Atypical haemolytic uraemic syndrome (aHUS) is a rare disease predominantly caused by alternative complement pathway dysregulation. Prior to 2011, before the targeted complement inhibitor eculizumab became available, aHUS frequently led to end-stage kidney disease (ESKD) and early death. Treatment with eculizumab led to notable improvements in outcomes; whether patient characteristics and management has continued to change over time is unknown. Using data from the Global aHUS Registry, we assessed clinical characteristics and management of patients with aHUS over 10 years to identify any potential trends.

Method: All patients enrolled in the Global aHUS Registry from 2012–2022 were included. Patients were categorised according to age at aHUS onset (adult [≥ 18 years] vs paediatric [< 18 years]); onset of aHUS was defined as the earliest of initial symptom presentation, aHUS diagnosis, or first recorded thrombotic microangiopathy (TMA). Patient characteristics were summarised using descriptive analysis.

Results: Of the 1994 patients enrolled in the registry between 2012 and 2022, 33 (1.7%) were missing data on age at aHUS onset. Of the remaining 1961 patients, 813 (41.5%) were paediatric and 1148 (58.5%) were adult. Changes in patient characteristics and management are presented in Fig. 1. Plasma exchange/plasma infusion (PE/PI) prior to and including the year of enrolment was less common in paediatric than adult patients (58.5% vs. 71.3%) between 2012–2013 and declined substantially in paediatric (19.6%) relative to adult (55.1%) patients by 2020–2022. Similar proportions of paediatric patients required dialysis at the time of enrolment between 2012–2013 (5.1%) and 2020–2022 (6.5%), while numerically lower proportions of adults required dialysis over time (2012–2013, 15.2%; 2020–2022, 6.5%). The rate of paediatric patients requiring a kidney transplant prior and up to enrolment dropped from 2012–2013 (28.4%) to 2020–2022 (5.9%); however, the rate among adult patients remained comparable (2012–2013, 29.2%; 2020–2022, 27.1%). A decrease in the proportion of patients with a reported identified pathogenic variant and/or anti-CFH antibodies was observed in paediatric and adult patients between 2012–2013 (paediatric, 59.1%; adult, 45.5%) and 2020–2022 (paediatric, 49.0%; adult, 38.8%). The proportion of patients with a reported triggering event increased from 2012–2013 (paediatric, 6.3%; adult, 12.4%)
to 2020–2022 (paediatric, 9.8%; adult, 28.0%). In this cohort, a total of 1208 patients were treated with eculizumab/ravulizumab between 2012 and 2022 (paediatrics, 476; adults, 732). Between 2012–2013, the median time from aHUS onset to treatment initiation was 94.9 days for paediatric patients (blue) and 51.1 days for adult patients (orange); this fell to 13.1 days in paediatrics and 24.1 days in adults between 2020–2022 (Fig. 2).

**Conclusion:** Utilisation of PE/PI to treat aHUS has decreased more in paediatric than adult patients over time. A decreased requirement for transplant in paediatric patients was evident, suggesting more paediatrics are now being diagnosed and treated earlier, leading to better outcomes with fewer patients progressing to renal failure and requiring kidney transplant. The proportion of both paediatric and adult patients with reported pathogenic variants and/or anti-CFH antibodies decreased over time and may reflect

*Figure 1:* Changes in characteristics of patients in the Global aHUS Registry.

*Figure 2:* Gap between aHUS onset and treatment start for patients in the Global aHUS registry.
the rate at which a clinical constellation consistent with aHUS is identified. Moreover, aHUS may not be recognised as frequently in the presence of a triggering condition, or a lower barrier for clinicians to suspect aHUS in recent years. Patients were more rapidly treated with a complement inhibitor, likely due to better awareness in the clinical community around complement inhibitors and the importance of early treatment initiation. Although patients with aHUS are being treated more promptly in recent years than 10 years ago, more work is needed, especially in adults, to move towards optimal clinical practice.

#3169 EXPERIENCE IN INTRAOPERATIVE AUTOLOGOUS BLOOD SALVAGE IN PEDIATRIC CARDIAC SURGERY
Bratislav Stankovic¹, Gordana Vidakovic² and Željko Vidakovic³
¹The high school of professional health studies, Zemun, Belgrade, Serbia, ²Special Hospital for Cerebral Palsy and Developmental Neurology, Belgrade, Serbia and ³Livanova, Italy

Background and Aims: Due to the drastic reduction in the number of voluntary blood donors has led to the need for the development of alternative strategies for allogeneic blood transfusion, which include the use of different strategies for autologous transfusion. Display: a) the use of "Cell-Saver" pediatric cardiac surgery at the Department of Cardiothoracic Surgery, Institute for Health Protection of Mother and Child of Serbia; Dr Vukan Cupić; b) to analyze the reduced use of allogeneic blood and/or chemo products using "Cell-Saver" pediatric cardiac surgery; c) to evaluate the "cost benefit" of this strategy (e.g. the ratio of prices set, "Cell-Saver") and pretransfusion rates processing one unit of allogeneic blood; d) to identify increased intraoperative security in complex, reconstructive and redo cardiac surgery using the "Cell-Saver" combined with ultrafiltration (conventional or modified), particularly in cyanogenic congenital heart defects; e) to establish and improve the hemodynamic status of hemoreologic operated child.

Method: A retrospective study was conducted. Experimental group included 63 patients (aged 12 years - 16 years and 4 months, body weight of patients that ranged between 2.9 kg and 80 kg - the mean body weight was 28.3 kg). In the experimental group patients were performed following cardiac surgery: 46 patients underwent reconstructive surgery (most often reparations for cyanogenic congenital heart defects); 3 patients who underwent cardiovascular, and 3 patients who underwent cardio-surgical procedures had hematological disorders. The control group included 60 patients of similar age and body mass who underwent the cardio-surgical procedure without the use of "Cell-Saver" with application of allogeneic blood and/or chemo products during transfusion care. The following laboratory parameters were accompanied: hematocrit, platelet count, fibrinogen, prothrombin time (PT) and activated partial thromboplastin time (aPTT), after 3, 6, and 12 hours postoperatively compared to the control group. We compared the volume of postoperative bleeding by patients of the experimental group with the control group (1h, 4h, 7h, 11h, 15h, 21h and 24h) and analyzed the amount of used allogeneic and autologous blood and/or hemoglobin products used in the transfusion care during hospitalization the experimental group compared with the control group.

Results: Postoperative administration of allogeneic blood and/or hemoproducts was statistically significantly lower in the experimental group using "Cell-Saver" than in the control group. The amount of salvaged blood after surgery ranged from 210 ml - 620 ml. Intraoperative hematocrit "rescued" autologous blood ranged between 0.32 / 1/l and 0.38 / 1/l. e range of values preoperative and postoperative hematocrit were lower in the experimental group than in the control group that used "Cell-Saver". The total volume of postoperative drainage content was significantly lower in the experimental group, which used "Cell-Saver" compared to the control group. The postoperative hematocrit was higher in the experimental group patients who used "Cell-Saver", compared with the same operating using allogeneic blood and/or hemoproducts patients in the control group. The mean platelet count, fibrinogen, PT and aPTT results showed no statistically significant difference between the experimental group of patients in whom we used "Cell-Saver" in comparison to the control group.

Conclusion: The results obtained by the retrospective analysis of above mentioned data indicate a positive therapeutic effect of the application of the "Cell-Saver" that is most clearly expressed in patients with the presence in the "bell" of small volume, the use of the Cell Saver has become an integral part of the pediatric cardiac surgery - perfusion, regardless of body weight, age and body surface area of the child. The performance of intraoperative "rescue" of autologous blood using the "Cell Saver", while the follow-up of pediatric patients in the perioperative and postoperative period has immeasurable significance of teamwork perfuser, expert specialist nursing, pediatrician, cardiac surgeon and transfusion.

#3713 NEPHROLOGISTS’ AND PRIMARY CARE PHYSICIANS’ KNOWLEDGE ABOUT NOVEL TREATMENT OPTIONS FOR TYPE 2 DIABETES AND CKD AUGMENTED BY ONLINE MEDICAL EDUCATION
Joachim Trier¹, Jolanta Malyszko² and Rita Moreira Da Silva³
¹WebMD Global LLC, Medscape Education, New York, United States of America and ²Medical University of Warsaw, Department of Nephrology, Warsaw, Poland

Background and Aims: Diabetes is the number one cause of kidney failure and chronic kidney disease (CKD) associated with type 2 diabetes (T2D) increases the risk for cardiovascular events 2 to 3-fold thus highlighting the crucial need for early detection of CKD and comprehensive vascular risk control. Recently, novel treatment options with clear benefits for the prognosis of patients with T2D and CKD have emerged. The goal of this activity for primary care physicians (PCP) and nephrologists (NEPH) was to improve their understanding of the clinical benefits as well as safety considerations of selective non-steroidal mineralocorticoid antagonists (sMRA) in the management of their patients with T2D and CKD.

Method: Two nephrology experts joined a 20-minute online video discussion in the synchronization slides. Educational effect was assessed using a repeated-pair design with pre-/post-assessment. 3 multiple choice questions assessed knowledge, 1 question rated on a Likert-type scale assessed confidence. A paired samples t-test was conducted on overall average number of correct responses and for confidence rating, a McNemar's test was conducted at the question level (5% significance level). Cohen’s d with correction for paired samples estimated the effect size of the education on number of correct responses. Data collection from 8/2/22 to 10/17/22.

Results:

• 42% of PCP (n=212, p<.001, d=0.36) and 35% of NEPH (n=146, p<.001, d=0.31) improved their knowledge regarding the clinical benefits and safety aspects of novel selective sMRA for patients with T2D and CKD
• 47% of PCP and 37% of NEPH had greater confidence (score increased by 73% and 50%, respectively) in their ability to treat patients with CKD and T2D with a selective sMRA
• 92%/93% of participating PCP and 96%/97% of NEPH expect that the education will improve their performance and patient outcomes.

Conclusion: Participation of PCP and NEPH in an online video expert discussion improved their understanding of the clinical benefits and safety aspects of selective sMRA as well as their confidence in using such novel therapies for their patients with T2D and CKD in clinical practice.

#3739 SHUNT PORTOSYSTEMIC COMPLICATED BY HYPERAMMONEMIA AND HEPATIC ENCEPHALOPATHY SUPPORTED BY DAILY DIALYSIS IN A CHRONIC HEMODIALYSIS PATIENT
Nabil Hamouche, Sara Bouhjar, Mariam Chettati, Wafaa Fadili and Inass Laoud
Mohammed VI University center of Marrakesh, Nephrology, Marrakech, Morocco

Background and Aims: Hepatic encephalopathy is a neuropsychiatric syndrome that may develop as a consequence of liver insufficiency. In acute liver failure, hepatic encephalopathy suggests the severity of the disease. In end-stage chronic liver diseases, episodes of hepatic encephalopathy are frequently fully and spontaneously reversible. Clinical manifestations vary from mild neuropsychiatric disorders to coma. The pathogenesis of hepatic encephalopathy is complex and not clearly understood. Ammonia plays a key role. In the healthy individual, ammonia is, during its first hepatic passage, directly degraded into urea, itself excreted by the kidney and the stools, and to a lesser degree in glutamine. Ammonia is also metabolized by the muscle stripped. In case of liver failure and/or shunts portosystemic, there is a defect in hepatic clearance ammonia which is then found in excess in systemic circulation. Decreased muscle mass, linked to malnutrition, frequent
in the patient cirrhotic and chronic hemodialysis, also helps to decrease brain barrier, the brain is exposed to excessive concentrations ammonia causing functional brain abnormalities and structural, which can partly explain the signs neurology of hepatic encephalopathy. In end stage chronic renal failure, clearance of ammonia via extracorporeal treatment has not been systematically evaluated. Several studies with small samples have demonstrated the effectiveness of hemodialysis, compared to peritoneal dialysis, in terms of ammonia elimination in chronic renal failure, on dialysis or not on dialysis.

The aim of this study was to evaluate the effectiveness of daily dialysis for the purification of ammonium a chronic hemodialysis patient with hepatic encephalopathy.

Case Report: A 40-year-old man undergoing chronic hemodialysis was referred to gastroenterology department of Mohammed VI University Center of Marrakech for inoperable shunt portosystemic complication by hyperammonemia causing hepatic encephalopathy consisting of headaches and seizures. His medical history was significant for liver cirrhosis caused by infection with hepatitis B, end stage kidney disease due to membranoproliferative glomerulonephritis, for which the patient is on hemodialysis at the rate of 3 sessions per week.

The patient went on to develop portal hypertension and ascites requiring frequent hospital admissions and treatment with diuretics. He was on a low-protein and low-sodium diet. While on oral furosemide 250 mg daily and spironolactone 100 mg daily, his diuresis was adequate. Before referral, this patient had already suffered 4 episodes of tonic clonic seizures. His 1st hemodialysis session in our training was on January 10, 2023, he was given daily hemodialysis sessions with daily blood tests, including immediate pre and post dialysis ammonia. Pre-dialytic ammonia levels varied between 24 and 37 μmol/l, as well as post-dialytic ammonia levels varied between 103 and 161 μmol/l, knowing that the normal value of laboratory ammonia varied between 10 and 31 μmol/l.

The evolution was marked by a clear clinical improvement, with a disappearance of the seizures without a significant drop in ammonia after 14 daily hemodialysis sessions. Serum creatinine and urea declined, and sodium increased. Accumulation of ascites slowed and the patient could eat and sleep normally and was again independent with self care. The patient returned home on January 24.

Conclusion: This study shows the interest of daily hemodialysis sessions as a potential treatment for hyperammonemia in a patient on chronic intermittent hemodialysis, with a portosystemic shunt. The interest lies in the fact that the improvement is mainly clinical than biological (persistent hyperammonemia).

ASSESSMENT OF THE PROGRESSION OF CKD TAKING INTO ACCOUNT METABOLIC CHANGES

Guzal Karimdzhanova, Dano Egamberdieva and Iroda Ruzmetova
Tashkent Pediatric Medical Institute, Internal Disease, Nephrology and Hemodialysis, Tashkent, Uzbekistan

Background and Aims: To study was to study the relationship between the metabolic syndrome and the risk of CKD progression in a representative sample of patients who were hospitalized at the Department of Cardiology and Interventional Cardiology of the Republican Specialized Scientific and Practical Medical Center for Therapy and Medical Rehabilitation.

Method: In the prospective part of the study, information on demographic characteristics, including age, gender, education, and occupation, was collected from doctor’s visits using a standard questionnaire. Metabolic syndrome was defined according to international guidelines in the presence of three or more of the following risk factors: waist circumference > 102 cm in men or > 88 cm in women; serum triglyceride level ≥ 1.70 mmol/l; HDL cholesterol level < 1.04 mmol/l in men or < 1.30 mmol/l in women; BP ≥ 130/85 mm Hg, including achieved serum glucose level ≥ 6.11 mmol/l. The criteria for determining the metabolic syndrome were used.

Results: Demographic characteristics of patients are presented in the table. Mean serum creatinine was similar, but GFR was estimated to be lower among those with metabolic syndrome compared to those without. The percentage of individuals with CKD and elevated serum creatinine was statistically significantly higher among those with metabolic syndrome. It turned out low HDL cholesterol, elevated plasma glucose and abdominal obesity were statistically significantly associated with the risk of developing C5 CKD and elevated serum creatinine. In addition, there was a significant relationship between the number of metabolic syndrome components and the percentage of C5 CKD or elevated serum creatinine (P < 0.015 and P = 0.02, respectively). In the multivariate model, patients with 1, 2, 3, and 4 or 5 components of the metabolic syndrome had 1.51; 1.50; 2.13 and 2.72 times higher chances of C5 CKD, respectively, compared to individuals without metabolic syndrome components. Overall, patients with metabolic syndrome had a 64% increase in risk of C5 CKD compared to the comparison group without metabolic syndrome.

Conclusion: In the present study, a positive and significant relationship was found between the metabolic syndrome and the risk of C5 CKD in the examined patients. The risk of C5 CKD increased progressively with an increase in the number of components of the metabolic syndrome.

SERENDIPITY OF SGLT2 INHIBITION – DIABETIC AND NON DIABETIC CKD
Vjollca Godanci-Kelmendi1,2, Mimoza Ramadani Piraj3, Fatime Ymeri1 and Shega Konjufca4
1 UCCK, Nephrology Clinic, Prishtina, Kosovo*, 2 UCCK, Nephrology Clinic, Prishtina, Kosovo*, 3 UCCK, Endocrinology Clinic, Prishtina, Kosovo* and 4 Asklep Med, Ministry of Health Private Practice, Prishtina, Kosovo*

Background and Aims: Ever since their therapeutic introduction, SGLT2 inhibition class of medicaments did impress physicians of related fields, nephrologists, internal medicine doctors, endocrinologists etc. Their natriuretic and glucoretic effects besides lowering the plasma glucose does produce a important effect on lowering intraglomerular pressure, this became an added value and a strong point to recommend these drugs on all CKD population irregardless the main cause of the disease.

Method: Observational retrospective study on 125 patients, three groups: G1 50 pt with diabetic nephropathy treated with empagliflozine vs control group G2 50 pt with diabetic nephropathy treated with other glucose lowering agents, and G3 25 nondiabetic pt with CKD and proteinuria treated with SGLT2i. Inclusion criteria was proteinuria and T2D for G1 and G2, and patients with proteinuria and CKD for G3. Patients with T1D and eGFR > 20 where excluded. Intervention - the SGLT2i drugs where started, median follow up 18 months. We followed on four periods creatinine levels, 24 hour proteinuria in g/24 h, HbA1c, cholesterol level, BMI.

Results: In our study the G1 showed a decrease in proteinuria average – 811 mg/24 h, serum creatinine showed increase on the first three months and it did get back to baseline afterwards, the eGFR increased + 15.44 ml/min; Hba1c decreased with -1.41%, levels, the reduction BMI – 0.9 kg/m² and LDL cholesterol -1.11 mmol/L. G2 results decrease on 24 hour proteinuria with – 121 mg/24 hours, a drop on eGFR with - 3.3 ml/min, a drop on HbA1C – 1.45 %, - 0.3 mmol/l decrease on cholesterol level and average increase on BMI with + 0.8 kg/m²; G3 results on patients without T2D but with CKD different causes and proteinuria where: - 690 decrease proteinuria, + 14.4 increase on eGFR, Hba1C NA, we did have 2 cases that experienced hypoglycemic symptoms, both of them where improved with dose reduction, a – 0.9 decrease on cholesterol level and 0.3 kg/m² was registered on our G3.

Conclusion: In our observation the 18 month follow up showed remarkable improve in kidney function tests, other benefits were noted such as optimal glycemic control, total body cholesterol lowering and a significant reduce of body weight expressed on BMI. Treatment with SGLT2i drugs does present a safe and efficient treatment modality for diabetic nephropathy and for all other CKD with proteinuria.

**DARBEPOETIN ALFA ONCE IN 4 WEEKS CORRECTS ANEMIA IN PATIENTS WITH CHRONIC KIDNEY DISEASE NOT ON DIALYSIS**

Mooyong Park¹, Soo Jeong Choi² and Jin Kuk Kim³

¹Soonchunhyang University Bucheon Hospital, Bucheon, Rep. of South Korea

**Background and Aims:** In anemia management in patients with CKD not on dialysis (CKD ND), darbepoetin alfa (DA), which has shorter half-life but lower cost than continuous erythropoietin receptor activator (C.E.R.A.), is preferred in actual clinical practice in Korea. The current study evaluated the efficacy and safety of DA every 4 weeks (Q4W) compared to C.E.R.A. Q4W administration for in erythropoiesis-stimulating agent (ESA)-naive patients with CKD ND.

**Method:** In this randomized, prospective, non-inferiority study, 40 ESA-naive patients with CKD ND were randomized 1:1 to receive either DA or C.E.R.A. Q4W during a 12-week correction period and 24-week efficacy evaluation period (EEP). Two primary efficacy end points were analysed: 1) the mean difference in the changes in haemoglobin (Hb) levels between baseline and EEP and 2) the Hb response rates defined as the proportion of patients who reached the target Hb level range (10-11 g/dL) during correction period. The non-inferiority margin is pre-defined as: 1) The lower limit of the 95% confidence interval (CI) is > -0.75 g/dL for the mean difference in the changes in Hb levels and 2) >60% for Hb response rates. Safety profiles including changes in blood pressure (BP), laboratory safety parameters, and frequency of all adverse events (AEs) were monitored and analysed during study period.

**Results:** The mean difference in the changes in Hb levels between the two groups was [0.375 g/dL; 95% confidence interval (CI), -0.446 to 1.196] and [-0.070 g/dL; 95% CI, -0.730 to -0.590] in the intent-to-treat (ITT) and per-protocol (PP) population, respectively (Fig. 1). The Hb response rates in correction period were comparable between DA and C.E.R.A. group; [100%; 95% CI, 81.4 to 100] versus [94.1%; 95% CI, 71.3 to 99.8] and [100%; 95% CI, 79.4 to 100] versus [100%; 95% CI: 88.2 to 100] in ITT and PP population, respectively (Fig. 2). The mean estimated glomerular filtration rate, systolic and diastolic BP, sodium, and potassium level over time were not different during total study period between two groups (P = 0.264, 0.999, 0.823, 0.941, and 0.978). All of the AEs in each group were reported to be mild to moderate in intensity. Peripheral edema, neck pain, herpes zoster, and dyspnea occurred in DA group (20%) and urinary tract infection, dyspnea, and femur neck fracture occurred in C.E.R.A. group (15%). There were no serious AEs which led to discontinuation of the treatment. All AEs were mild to moderate in severity, and they are probably not associated with the study drugs and were successfully cured. The reasons for discontinuation of the drugs were starting HD or follow-up loss, but not due to the administered study drugs. No subjects received RBC transfusion or iron replacement therapy in both groups. There was no death during the study period.

**Conclusion:** These study results suggest that DA Q4W has non-inferiority in anemia correction efficacy and similar safety profiles compared to C.E.R.A. Q4W in ESA-naive patients with CKD ND.

---

Figure 1: The mean difference in the changes in Hb levels with Darbepoetin alfa (DA) and continuous erythropoietin receptor activator (C.E.R.A.) between baseline and evaluation period (ITT and PP populations). ITT, intent-to-treat; PP, per-protocol.
Supplemented low-protein diet (sLPD) versus a conventional diet on the is a comparative study that aimed to assess the effects of a ketoanalogue-supplemented low-protein diet (sLPD) versus a conventional diet on the progression of CKD and proteinuria in patients with advanced DKD.

**Background and Aims:** Low-protein diets seem to have an important role in the management of advanced chronic kidney disease (CKD). In addition, this type of nutritional regimen may defer kidney replacement therapy by improving metabolic abnormalities. However, low-protein diets (LPDs) may be more difficult to integrate in patients with diabetic kidney disease (DKD), because of the already complex dietary intervention in these patients. This is a comparative study that aimed to assess the effects of a ketoanalogue-supplemented low-protein diet (sLPD) versus a conventional diet on the progression of CKD and proteinuria in patients with advanced DKD.

**Method:** Ninety-seven adult patients with DKD and heavy proteinuria (>3 g/g creatininuria) who proved to be compliant to protein restriction in a 3-month run-in phase were enrolled to receive a LPD (0.6g mixed protein/kg-day) supplemented with ketoanalogues of essential amino acids (Ketosteril®, Bad Homburg, Germany, 1 tbl/10 kg dry ideal body weight per day) for 12 months. Ninety-two patients completed the study (5 patients received preemptive kidney transplant). The control group was made up of seventy-four adult patients with DKD and heavy proteinuria who received a conventional diet for 12 months. Efficacy outcomes were variation of the estimated glomerular filtration rate (eGF) and variation of proteinuria.

**Results:** At baseline, patients from the sLPD group had a median age of 61 years (95% CI 58 to 67), were mostly male (66%) and predominantly on insulin (68%). In the control group, the median age of 60 years (95% CI 56 to 61), 62% were male and, similarly, the majority were on insulin (62%). All patients had poorly controlled diabetes, with a glycated hemoglobin of 8.1% (95% CI 8.0 to 8.3) in the sLPD group and 8.2% (95% CI 7.9 to 8.6) in the conventional-diet group respectively (P = .84). Although the median eGF was different between groups: 24.78 mL/min (95% CI 20.00 to 30.00) in sLPD patients versus 12.61 mL/min (95% CI 11.70 to 13.11) in conventional diet patients (p < 0.0001), proteinuria was similar at baseline: 5.26 g/g creatininuria (95% CI 4.98 to 5.22) in sLPD patients and 4.05 g/g creatininuria (95% CI 3.70 to 5.80) in control group patients (P = .44). After 12 months, the decline of eGF (mL/min/month) was four-times slower in the sLPD group versus the control group [0.11 (95% CI 0.1 to 0.14) versus 0.43 (95% CI 0.30 to 0.57), p < 0.0001]. A twofold reduction in proteinuria (g/month) was observed in sLPD patients compared to conventional diet patients [0.29 (95% CI 0.28 to 0.32) versus 0.12 (95% CI 0.09 to 0.15), p < 0.0001].

**Conclusion:** Low-protein diets supplemented with ketoanalogues of essential amino acids seem to be more efficient in reducing kidney function decline and proteinuria than conventional diets.

**DUAL DIALYSER HAEMODIALFILTRATION: A NEW EXTRACORPOREAL DIALYSIS TREATMENT MODALITY FOR PATIENTS WITH END STAGE KIDNEY DISEASE**

Gerald Glancey

1 Ipswich Hospital, Renal unit, Ipswich, United Kingdom

**Background and Aims:** The introduction of High Flux (HF) haemodialysers and their application in single dialysers haemodialfiltration (sdHDF) for patients on extracorporeal dialysis (ECD) therapy has improved the extraction of ureaemic toxins including the low molecular weight protein (LMWP) beta 2 microglobulin (#2M, 11.6kDa). Similar increases in the extraction of protein-bound ureaemic toxins (PBUT) and larger LMWP (15-50kDa) remain elusive. High concomitant losses of albumin prohibit the use of Medium Cut-Off (MCO) or protein-losing haemodialysers in sdHDF to increase the convective transfer of these molecules.

**Method:** A new extracorporeal dialysis treatment modality, dual dialyser haemodialfiltration (ddHDF), has been designed together with an accompanying mathematical model to compare its predicted performance to that of sdHDF in the extraction of solute. The extra process that distinguishes ddHDF from sdHDF is the secondary ultrafiltration and partial re-infusion of the effluent haemodiafiltrate from the initial or primary haemodialyser. This allows MCO and protein-losing haemodialysers to be used to increase the extraction of both LMWP and PBUT without excessive concomitant loss of albumin.

Glancey GR. Modeling the transfer of low molecular weight proteins during haemodialfiltration and online haemodialfiltration. *Artificial Organs* 2021;45(4):419-426.

**Results:** Data from the mathematical model show that ddHDF could increase the extraction of smaller and larger LMWP by an extra 102% and 220% respectively compared to standard HF sdHDF whilst restricting the loss of albumin to 0.83 grams per hour of treatment. In using albumin as a recyclable carrier molecule for the extraction of PBUT from plasma ddHDF has the potential to increase PBUT reduction ratios (RRs) to 49% by convection alone. Even higher RRs are possible if the dialysate volume flow rate can be increased beyond 600 ml/min.
Conclusion: ddiHDF provides an opportunity for a step change increase in the level of extraction of both larger LMWP and PRMT in patients with end stage kidney disease.

#5633
USE OF HEPARIN GRAFTED DIALYZER (EVODIAL) FOR HEMODIALYSIS IN PATIENTS WITH HIGH RISK OF BLEEDING: A SINGLE CENTER EXPERIENCE

Vladimir Pusheski, Zhaklina Shterjova- Markovska, Julijana Usprcov, Nikola Gjorgjievski, Lada Trajcheska, Mimoza Milenkova and Irena Rambabova-Bushnjletik
University clinic for nephrology- Faculty of Medicine, Ss. Cyril and Methodius University, Skopje, Republic Of North Macedonia

Background and Aims: During hemodialysis exposure of the blood to the dialysis membrane and the tubing system can activate blood cells and promote clotting activation. So usually, some form of anticoagulation, most frequently heparin, is used to prevent blood coagulation. However, there are patients with increased risk for bleeding (patients with active bleeding, major surgery in past 72 hours, severe trombocytopenia) where use of heparin free regime is mandatory. Evodial dialyzer (Gambro-Hospital, France) [1] contains a heparin-grafted membrane aiming to provide a system with a low thrombogenicity that can be used without or with low dose heparin in order to reduce the patients’ bleeding risk. As high-quality evidence of the optimal choice of anticoagulation in these patients is limited we wanted to show our experience with the use of Evodial dialyzer.

Method: During 12 months 106 dialysis sessions in 59 patients were performed. Reasons for using Evodial : active bleeding, hematological conditions, complications of vascular access. Changes in the dialyzer or the blood lines, or any additional interventions were examined.

Results: Low dose unfractionated heparin (1250 IE total) was used in 10 (9.4%) sessions, and it was added in 15 (14%) more sessions because of problems with the coagulation. In 4 (2.8%) sessions we had to terminate dialysis because of clotting.

Conclusion: Heparin grafted dialyzers can be safely used in patients with high risk for bleeding. Although results are worse than the ones reported in literature [2] where regional citrate anticoagulation (RCA) is used, it can be reasonable alternative when RCA is unavailable.

THE INCESSANT QUEST FOR DRY WEIGHT: SHOULD WE ADOPT NEW STRATEGIES?

Amel Ayed, Hadj Brahim Mayssa, Lazhar Jaballah, Amel Echouk, Habiba Ben Alaya and Zohra Elati
Taher Safar Hospital, Nephrology, Mahdia, Tunisia

Background and Aims: The estimate of the hydration state in the chronic hemodialysis patient is a key point of his care. Currently, there is no Gold Standard feasible in routine despite the increasingly numerous tools such as impedancepenetry and pulmonary cardiac ultrasound.

The objective of our study is to compare the results of the clinical estimation of dry weight with the results of impedancepenetry and cardiac ultrasound results.

Method: This is a transverse study in the dialysis unit of Taher Safar Mahdia hospital. The estimation of the hydration state was assessed before and after the hemodialysis session by the three above methods. The volume evaluation was carried out by a clinical score (NYHA= III dyspnea, orthopneic; jugular turgor (TJ), hepatojugular reflux (HRJ), crackling in auscultation, peripheral edema and pre-dialysis hypertension); as well as by cardiac ultrasound (diameter of the lower vein, E/E ratio and systolic pulmonary arterial pressures).

Results: The values measured by the different techniques decreased significantly after the hemodialysis session (p <0.001). At the two -stroke studied, we have objectified a significant correlation between the results of the impedancepenetry, the index of the lower vein and its compliance. A significant difference between the results provided by the techniques studied and the results of the clinical evaluation was found in 64 % of patients. Only the orthopnea (p = 0.03) and the hepatojugular reflux (p = 0.04) were significantly associated with the ultrasound overdiagnosis.

Conclusion: The existence of a difference between the subjective and objective target weight suggests the incessant need for a mixture between the different techniques evaluated. Our strategy requires to be adapted to the particularities of each patient.

#4431
PREPARATION OF IMIDAZOLE QUATERNARY AMMONIUM SALT MICROSPHERES WITH HIGH BILIRUBIN ADSORPTION PERFORMANCE AND SELF-ANTICOAGULATION ABILITY

Ningyue Deng, Lunqiang Jin2 and Baihai Su2
P.R. China and , P.R. China

Background and Aims: Bilirubin is a crucial toxin in liver metabolism. Increase of bilirubin is one of common manifestations in patients with abnormal liver function, and large accumulation of bilirubin in the blood can lead to more severe hepatic dysfunction and even death. Due to the poor therapy effect and the shortage of available donor organs, the artificial liver support system has been introduced to maintain the liver function and bridge patients to transplantation. Previous studies have found that imidazole quaternary ammonium salts have great potential to adsorb bilirubin. This work is to develop a novel bilirubin adsorption column by simple and general method, and evaluate the removal efficiency, anticoagulant property and biocompatibility of the bilirubin adsorption column.

Method: Multifunctional microspheres were fabricated by in situ polymerization of 1-vinylimidazole and divinylbenzene. Nuclear magnetic resonance (NMR), thermo-gravimetric analysis and X-ray photoelectron spectroscopy (XPS) etc. were performed to characterize the chemical compositions of the microspheres. Meanwhile, hemolysis test, blood routine test and clotting time test etc. were leveraged to evaluate the biocompatibility of the microspheres. Both static adsorption test and dynamic adsorption test were performed in vitro to evaluate adsorption performance.

Results: A variety of methods had proved successful synthesis of the adsorption performance. The hemolysis ratios of microspheres were less than 5%. Compared with BS330 microspheres and PES microspheres, the activated partial thromboplastin time (APTT) and thrombin time (TT) were longer in this work. Moreover, the microspheres showed a high adsorption clearance. In PBS solution of bilirubin, the adsorbent could decrease bilirubin from 200 mg/L to 45-55 mg/L.

Conclusion: The results suggested that the multifunctional microspheres can significantly reduce bilirubin concentration without obvious adverse interactions and could exhibit anticoagulation activity.

#4059
MICROBIOLOGICAL ANALYSIS OF HEMODIALYSIS WATER AT THE DOUALA GENERAL HOSPITAL, CAMEROON

Cedric Gueguim, Alain Ragon1, Halle Marie Patrice3, Francois Jerome Kaze Folefack1 and Hortense Gonsu Kamga1
Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Central region, Cameroon, Microbiology, Cameroon, 1Division of Uro-Nephrology Laboratory, Hospital of Conception, Marseille, France, pharmacology, France, 3Faculty of Medicine and Pharmaceutical Sciences, University of Douala, Littoral Region, Cameroon, Nephrology, Cameroon and 4Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Central region, Cameroon, Cameroon

Background and Aims: Rigorous control of the microbiological quality of water in hemodialysis services is important because the immune system of patients with chronic renal failure is weakened. The aims of this study was to determine the microbiological quality of water for hemodialysis in Nephrology Unit of the Douala Général Hospital in order to improve the disinfection strategy.

Method: Twelve water samples were collected each month at different sites of the hemodialysis circuits A (inlet of filters), B (Outlet of filters / inlet of Reverse Osmosis (RO) device) and C (outlet of the RO device / close to the generator) between November 2015 and February 2016 to be analyzed. The bacteria were isolated after filtration of 100 ml of water at each site through nitrocellulose membrane with 0.45 μm microporosity deposited on the surface of the Tryptone Glucose Extract Agar (TGEA) and then incubated at room temperature (20 to 22°C) for 7 days. After transplanting to different environments, pure bacterial isolates were identified by their cultural characters and marketed biochemical galleries.

Results: The colony count was well above the required international standards (>100 CFU / ml), for the hemodialysis water with a percentage of 50% of non-
compliance. Among the bacteria identified, seven (07) were Gram-negative bacilli including Pseudomonas fluorescens, and Klebsiella pneumoniae subsp. ozaenae, three (03) Gram-positive bacilli all Bacillus sp and three (03) Gram-positive cocci all of coagulase-negative staphylococci. The most frequently isolated bacterial genera were Pseudomonas sp (38,5%), Staphylococcus sp (23%), Bacillus sp (23%) and Klebsiella sp (15,5%).

Conclusion: The high bacteriological contamination of the hemodialysis water with the detection of a variety of bacteria shows that the disinfection procedure of the distribution loop is not efficient and cannot prevent the development of a biofilm. A higher frequency of disinfection (almost every week), an increase of the concentration and time of contact of the chlorine disinfection product or the use of peracetic acid and a regular monitoring can contribute to improve the quality of the hemodialysis water at the Douala General Hospital to ensure a better quality of life for patients undergoing this treatment.

#4837
CLINICAL OUTCOMES OF HEMOPERFUSION WITH MG350 AMONG RT-PCR-CONFIRMED SEVERE AND CRITICAL COVID-19 PATIENTS IN A TERTIARY HOSPITAL IN LA UNION
Mayene Alyssa Echave and Chrysanta Octaviano
Ilocos Training and Regional Medical Center, Internal Medicine, San Fernando City, The Philippines

Background and Aims: Hemoperfusion (HP) refers to the circulation of anticoagulated blood through an extracorporeal circuit with a disposable, adsorbent-containing cartridge. Earlier studies showed that HP stabilizes the plasma levels of cytokines in sepsis and septic shock. Case reports demonstrated the benefit of HP among COVID-19 patients with severe and critical illness but local data on the outcome of HP in COVID is still lacking. This study aimed to determine the clinical outcomes of HP with MG 350 cartridge among RT-PCR confirmed severe and critical COVID-19 patients admitted in a tertiary hospital in La Union in terms of the trend of clinical parameters before and after HP, mean duration of ventilatory support, mean duration of hospital stay and patient’s clinical parameters before and after HP. Patients with higher oxygen saturation, PaO2 and lower fraction of inspired oxygen (FiO2) had shorter duration of ventilatory support. Increased FiO2, CRP, D-dimer, ferritin, white blood cell (WBC) count and Neutrophil Lymphocyte Ratio (NLR) are highly correlated with increased mortality. Early hemoperfusion correlated with shorter duration of ventilatory support, shorter hospital stay and decreased mortality. Interestingly, those with higher oxygen saturation, PaO2, ferritin and procalcitonin correlated with longer duration of hospital stay after HP. Patients with critical illness and late HP had longer duration of ventilatory support. Patients with bilateral infiltrates on chest X-ray and those on mechanical ventilator had longer duration of hospital stay. Increased COVID severity and decreased mean arterial pressure (MAP) had higher likelihood of death even after HP.

Conclusion: Hemoperfusion significantly decreased the level of inflammatory markers thereby lowering the risk for cytokine storm for COVID-19 patients. Early HP is recommended as it is correlated with shorter duration of ventilatory support, shorter hospital stay and decreased mortality.

#5657
FRAILTY AND VASCULAR ACCESS IN HEMODIALYSIS PATIENTS
Eleni Intzevidou1, Charalampos Louradis1, Ourania Kougioumtzidou1 and Georgios Pitoulias2
1Dialysis Center Evangelismos, Veria, Greece and 22nd Department of Surgery, Gennimatas Hospital, Aristotle University of Thessaloniki, Division of Vascular Surgery, THESSALONIKI, Greece

Background and Aims: Frailty is a geriatric syndrome characterized by increased vulnerability to stressors. The elderly become vulnerable and susceptible to adverse outcomes for their health and to functional restrictions. Previous guidelines suggested fistula creation as first choice for vascular access. Current guidelines suggest a more tailored approach to the patient’s needs. Despite the high prevalence of frailty in hemodialysis patients, there is paucity of work investigating the relationship between frailty and vascular access failure. The aim of the study was the estimation of frailty with different scores and relationship with the choice of first vascular access, the current vascular access and vascular failures.

Method: 67 patients in hemodialysis participated to the study (observational cross-sectional study). Frailty was assessed with 6 different scores, Clinical Frailty Scale (CFS), Frailty Phenotype (FP), Edmonton Frailty Scale (EFS), Groningen Frailty Index (GFI), Short Physical Performance Battery (SPPB), PRISMA-7 and ankle-brachial index (ABI) and hand grip were also estimated. The current vascular access, the first vascular access, the vascular access failures and the mean duration of the vascular accesses were also recorded. Finally, the levels of the hemoglobin, albumin, C reactive protein, cholesterol were measured for all patients and the hemodialysis adequacy (URR, sp Kt/V) was calculated from the levels of urea before and after the hemodialysis session. Finally, the levels of the hemoglobin, albumin, C reactive protein, cholesterol were measured for all patients and the hemodialysis adequacy was calculated from the levels of urea before and after the hemodialysis session.

Results: The first vascular access of hemodialysis presents statistically significant relation between frail and robust patients that start hemodialysis with central venus catheter and AVF-AVG respectively. (SPPB- tunneled CVC 85, 7%, non tunneled CVC 46,2% p=0,032, PRISMA-7- frail tunnelled CVC 100%, non tunnelled CVC 76,9% p=0,018, Groningen FI -frail tunnelled CVC 100%, non tunnelled CVC 65,7% p=0,011, Edmonton FS -AVF-AVG not frail 64,7%, vulnerable 20,6% p=0,042) (Table 1-4). ABI presented a statistically

significant relationship with the current vascular access. 68.18% of the patients with normal ABI have AVF-AVG and 60.87% of patients with abnormal ABI have tunneled CVC (p=0.022). In addition, the number of vascular accesses per patient, the mean duration of the accesses and the premature failures (3 months after creation) don’t present statistically significant relation with frailty. Conclusion: The frailty score could be used as a tool for the choice of vascular access in hemodialysis patients. Further studies, in a larger number of patients, are required to define a reliable and easy to use frailty tool, which is best suited to dialysis access selection.

MAKING DECISION OF VASCULAR ACCESS TYPE BASED ON UPPER ARM DOPPLER PARAMETERS AMONG INCIDENT HEMODIALYSIS PATIENTS: A SINGLE CENTER EXPERIENCE
Aleksandar Jankovic1, Sofija Rajić2, Zeljko Davidovic1, Bojan Stopić1, Petar Djuric1, Snezana Pešić1, Radomir Naumovic1,2
1University Medical Center Zvezdara, Nephrology Department, Belgrade, Serbia and 2Belgrade University, Medical Faculty, Belgrade, Serbia

Background and Aims: Functional vascular access (VA) remains one of the most important problems related to successful hemodialysis (HD) treatments. Pivotal issue related to inadequate vascular access is decision making process of which type of VA should be created at start. Therefore, the aim of our study is to examine possible impact of Doppler examination of upper arm on decision of VA type creation.

Method: During 5 year period (January 2018th- December 2022th), 260 patients started hemodialysis in our department. Among them, 18 died during the first three months after HD was started, 3 were transferred to other hospitals for chronic HD program and 5 have created vascular access in other hospitals. So, we analyzed data for 234 patients (No. hospitals for chronic HD program and 5 have created vascular access in other hospitals. So, we analyzed data for 234 patients (No=150, 63.6% males, mean age 62.6±13.8) which vascular access were created in our Center. We have divided them into two groups (Group A-patients with arterio-venous fistula (AVF) as first created VA and group B-patients with arterio-venous graft (AVG) or permanent central venous catheter (pCVC) as first created VA. From medical records, we have collected demographic data, type of created vascular access, Doppler parameters of upper arm and laboratory findings.

Results: Out of 234 patients, in Group A were 167 patients (male No=109, 65.2%, mean age 61.0 years±13.8), while in group B were 67 patients(male No=40, 59.7% mean age 66.8 years±13.2). In table 1, demographic, laboratory and Doppler data is presented. We found that in Group A patients are statistically younger (61.0 years±13.8 vs 66.8 years±13.2, P = 0.004) and their vena cephalica (2.9mm± 2.5 vs 1.9mm±0.1, P = 0.000) and artery radialis (2.2mm±0.4 vs 1.9mm±0.1, P = 0.002) are with better diameters. Also, their protein levels were statistically lower (69±9 vs 78±3, P = .036) and CRP levels higher (21.2±35.3 vs 8.1±2.1, P = 0.000) compared to Group B. Binary logistic regression revealed that there are no statistically significant variables that could impact decision to create AVF, but larger diameter of vena cephalica increase this decision over 13 fold (OR 13.497, CI 0.706-257.868, P = .084), and diameter of artery radialis 17 fold (OR 17.073, CI 0.372-784.182, P = .146).

Conclusion: Diameters of vena cephalica and artery radialis could be the main variables in the planning of type of vascular access.

#5111
HEMODIALYSIS TUNNELED CATHETERS LOCK WITH TAUROLOCKTM VERSUS A COMBINATION OF GENTAMYCINE AND HEPARINE
Biser Borisov and Vanya Vasileva
Medical Universiti, Nephrology and Dialysis, Pleven, Bulgaria

Background and Aims: Catheter-associated infections (CAIs) and thrombosis (CAT) are the most common complications, associated with the use of tunneled catheters for hemodialysis. The incidence of infections is about 1.8-6.5/1000 catheter-days, and thromboses are the main cause of catheter dysfunction and loss of vascular access in 30-40% of patients. The aim of our study was to determine the incidence of these complications in patients in whom we used prophylactic "locking" of their tunneled catheters.

Method: The patients included in the study signed an Informed Consent (№29.06.2021) approved by the Research Ethics Committee at MU-Pleven. The study was conducted in the period of 01.03.2021 - 31.03.2022, a total of six months. The study included 23 men and 22 women with an average age of 60.82 (+/-13.629) years, and the age difference between the three groups can be considered insignificant (P = .046). All patients had tunneled catheters placed >3 months ago (mean duration was 714 +/- 247 catheter-days) as the only vascular access for hemodialysis treatment. After a clinical examination and a negative result of two blood cultures, the patients were randomly divided into three groups of 15 (fifteen) people each, a total of 45 (forty-five) participants: group A – locking the catheter only with TauroLockTM (Taupropharm, Waldbüttelbrunn, Germany), group B – locking with gentamicin (10 mg/ml) and heparin (1250 IU/ml) and group C – locking with TauroLockTM for three months, then – with heparin and gentamicin for the next three months of the study. Patients were monitored for the major complications of catheter-related infection (CRI) and catheter-related thrombosis (CRT). All data was statistically processed with Statgraphics 19.

Results: The median duration for tunneled catheters was 8,105 catheter-days (CD). One complication was reported in each of the three groups: group A – one case of CRI, groups B and C – one case of CRI each. No cases of catheter-associated bloodstream infection, requiring prolonged treatment and catheter thrombosis, requiring replacement of the tunneled catheter were reported. Reported costs for patients treated with TauroLockTM were calculated at 3 EUR/each dialysis session, and for patients treated with gentamicin and heparin – 0.88 EUR/dialysis session.

Conclusion: The data from our study unequivocally support the thesis that locking the catheter with a solution containing TauroLockTM is comparable to the effect of blocking the catheter with a solution containing an antibiotic and anticoagulant. In the short term, the difference in the price of medicines is significant, but it does not exceed the potential losses of public funds in the medium and long term. We recommend the use of a similar prophylactic regimen in all patients with tunneled catheters as the only possible vascular access for hemodialysis or with an expected duration of use greater than ninety days.

**EARLY DETECTION OF VASCULAR ACCESS STENOSIS USING NEPHROFLOW**

Soledad Pizarro Sanchez¹, Alejandra Elizabeth Collantes Toaza¹,², María López Picasso⁵, Eleno Burgos García¹, Saul Pampa Saico¹, Simona Alexandru⁵ and Laura García-Puente Suarez²

¹Hospital Rey Juan Carlos, Nephrology, Mostoles, Spain and ²Fundación Renal Íñigo Alvarez de Toledo, Nephrology, Spain

**Background and Aims:** The monitoring programs for vascular access make it possible to detect access dysfunction and indicate the need to perform an imaging test to confirm the presence of stenosis and proceed with its treatment. Measurement of arteriovenous fistula (AVF) flow using biosensors is a simple and reproducible method of vascular access assessment. AVF flow (QA) drops below 500 ml/min or a reduction of more than 25% in previous flow are considered predictors of stenosis and/or thrombosis. A stenosis with a high risk of thrombosis is defined as that which presents a decrease of more than 50% in the vascular lumen and a stenosis/prestenosis Peak Systolic Velocity ratio > 2, with additional criteria (residual diameter < 2 mm and/or QA (ml/min) < 500 (native AVF) or and/or decrease in QA > 25% if QA < 1,000 ml/min.

**Method:** We performed AVF flow measurement using the NephroFlow biosensor in prevalent hemodialysis patients.

**Results:** Sixty-one patients were studied, all with native or prosthetic AVF. Of which 42 men and 19 women. The distribution of AVFs was: 38 brachiocephalic (62%), 16 radiocephalic (26%) and 6 brachial-axillary (10%). The data was collected for 24 months. The mean follow-up time for the AVF was 16 months. In 17 patients (30%), flow was detected below 25% compared to previous controls or a decrease in QA < 500 ml/min. In these patients, echo-doppler was performed, showing in 15 cases stenosis with a high risk of thrombosis that was treated with angioplasty. In 1 patient, echo-doppler detected only insufficiency of the artery, and no stenosis was observed in fistulography. In 1 patient, there was a significant drop in flow (from 830 to 451 ml/min), which later recovered 650 ml/min with ultrasound without significant alterations, so an endovascular procedure was not performed. During the study period, 1 fistula thrombosis occurred in a patient who had already detected a drop in flow but could not repair it in time. At the end of the study, of the 61 patients analyzed, 51 patients continued with the technique and the flows remained stable or even increased. In the other 10 patients, 9 left due to transplantation or death and 1 patient had a new thrombosis and the AVF could not be repaired.

**Conclusion:** In hemodialysis units, the measurement of AVF flow using biosensors should be protocolized together with Doppler ultrasound to achieve better monitoring of vascular access, managing to detect and treat early stenosis with a high risk of thrombosis.

**SACUBITRIL/VALSARTAN IMPROVES THE VASCULAR ACCESS FLOW OF HEMODIALYSIS PATIENTS WITH HEART FAILURE AND REDUCED EJECTION FRACTION**

Chih-Ching Lin

Taipei Veterans General Hospital, Division of Nephrology, Department of Medicine, Taipei, Taiwan, Rep. of China

**Background and Aims:** Sacubitril/valsartan improved left ventricular systolic and diastolic function in patients with heart failure with reduced ejection fraction ≤40% (HFrEF) and end-stage kidney disease. However, there was no report concerning the effect of sacubitril/valsartan on access flow (Qa) of vascular access in maintenance hemodialysis (HD) patients with HFrEF. We aimed to investigate the effect of sacubitril/valsartan on Qa of vascular access in HD patients with HFrEF.

**Method:** We retrospectively screened the HD patients who received echocardiography and Qa measurement in Taipei Veterans General Hospital and Cheng Hsin General Hospital from Jan. 2019 to Dec. 2021. Patients with HFrEF received twice of both echocardiography and Qa at 1 year apart were enrolled and divided into two groups, including those with or without the treatment of sacubitril/valsartan. The difference of Qa at baseline and 1 year later was preferred. One previous study [2] identified physical concerns regarding fistulas as the predominant barrier preventing patients with a CVC from switching to an AVF. Here we provide an expansion on these barriers, alongside novel exploration of nursing opinion on access choice.

**Methods:** Data was collected through individually administered patient surveys across 4 regional dialysis sites in East Anglia (n = 380), and anonymised online survey requests to nursing staff at the sites. Deductive and inductive strategies were employed for analysis of the qualitative data. The aim of the thematic analysis was to determine the preferred access modality of patients and nurses, and the drivers for the preferences.

**Results:** 63% (n = 238) of patients responded to the questionnaire. Patient responses fell into one of four categories; drivers toward, or barriers against AVFs or CVCs. The largest of these categories was the barriers for AVFs, within which four main themes were identified: ‘Fear’, ‘difficult AVF surgery’, ‘patient preference for lines’ or ‘patients awaiting AVF surgery or transplant’. A smaller theme of ‘insufficient information’ regarding access choice was also identified. ‘Fear’ was the largest theme, within which five subthemes were identified: fear of needles, pain, bleeding, fistula appearance, or fear of complications heard from other patients on the dialysis unit. ‘Difficult AVF surgery’ encompassed two subthemes; those who have had previous failed traumatic attempts or those whose current vascular architecture was not amenable to fistula surgery. The other three categories received far fewer responses. The AVF driver category focused on fistulas being preferred medically with reduced infection risk, whilst drivers for lines included it being ‘comfortable’ and patients saying that the line works for them. The one comment in the CVC barrier category cited difficulties experienced with lines like blockages and infections. 13 responses were received from dialysis nurses. All respondents were aware of the medical preference for patients to have a fistula, and the reasons why. Nurses themselves also preferred their patients to have fistulas, referencing the same reasons. However, most nurses thought patients preferred CVCs, and were able to cite the same reasons as the patients themselves. Lastly, nurses reported that they convey the benefits and risks of different access types correctly when asked by patients at the dialysis units.

**Conclusion:** These findings highlight that, whilst doctors and nurses focus on long-term health benefits of AVF when discussing vascular access choices, patients are focussed on the immediate potential risks of an AVF. We hypothesise that, whilst dialysing, patients share stories of fistula-related complications that drive short-term fear of AVFs, with such impact that the messages conveyed by health professionals are often negated. This difference in agendas is essential to acknowledge. The relationship between clinician, nurse and patient in the haemodialysis setting is unique given its longevity, frequency of contact, and holistic nature. Implementing a strategy to bridge this agenda gap could strengthen this relationship and provide a basis for optimum, evidence-based treatment. We therefore suggest the use of positive patient AVF experiences, delivered via peer education sessions, as a tool to introduce drivers for, and uptake of, AVF for dialysis patients in the future.

**REFERENCES**

Figure 1: Sacubitril/valsartan group.

Figure 2: Control group.

compared by Wilcoxon signed-rank test, with a statistical significance of P<0.05.

Results: A total of 33 HD patients with HFrEF were analyzed with a mean HD vintage of 4.7 years. Sixteen patients received sacubitril/valsartan and the other 17 patients received conventional treatment. The mean Qa increased significantly from 633.8 to 948.8 mL/min (P<0.001) and the Qa change correlated with LVEF change [Fig. 1, correlation coefficient (r) =0.70, P=0.006] after 1-year treatment of sacubitril/valsartan; however, there was neither significant change of Qa (from 637.7 to 621.8 mL/min, P=0.44) nor correlation with LVEF change (Fig. 2, r=0.41, P=0.13) for controls after one year.

Conclusion: Sacubitril/Valsartan improves Qa in HD patients with HFrEF possibly related to the increase of LVEF.

THE ASSOCIATION AMONG CAROTID IMT, PWV AND VASCULAR ACCESS FAILURE IN HEMODIALYSIS PATIENTS
Jong-Woo Yoon1, Hyunsuk Kim2, Seokhyung Kim2, Gwangho Choi2, Jin-Up Kim2 and Youn-Ki Lee3
1Hallym University Medical center, Chuncheon Sacred Heart Hospital, Division of Nephrology, Department of Internal Medicine, Chuncheon, Rep. of South Korea, 2Hallym University Medical center, Chuncheon Sacred Heart Hospital, Division of Nephrology, Department of Internal Medicine, Rep. of South Korea and 3Hallym University Medical center, Kangnam Sacred Heart Hospital, Division of Nephrology, Department of Internal Medicine, Rep. of South Korea

Background and Aims: Patients with chronic kidney disease (CKD) or end stage renal disease (ESRD) have an increased risk of cardiovascular mortality and morbidity. We aimed to compare the value of IMT with tests such as coronary CT and Pulse wave velocity(PWV) as predictors of cardiovascular risk in ESRD patients undergoing maintenance dialysis and examine their association with cardiovascular disease.

Method: We reviewed the patients’ medical records, including height, body weight, smoking status, alcohol intake, medication history, etiology of ESRD, HD vintage, and blood pressure which were measured during hemodialysis. Carotid dopplerwas performed by an skilledsonographer who are unaware of the aims of the study and blinded to the laboratory findings. For PWV measurement, Patients lie down, rest for at least 5 minutes, and prohibit smoking and coffee for 3 hours before the measurement. BaPWV is measured by recording pulse waves of both arm and both ankles from the pressure signal obtained by measuring 4-extremity blood pressure.

Results: One hundred patients were included, of whom 51 (50.5%) were men. The median age was 66 years (interquartile range 58-76 years). The median vintage of hemodialysis was 47.5 months (range 31.3-89.1 months). There were no significant differences between high IMT groupand low IMT group in sex, hemodialysis vintage, end-stage renal disease etiology, and type of vascular access. However, age was significantly older in the high IMT group. IMT was significantly associated with PWV (hazard ratio [HR] 2.109, 95% CI 1.037-4.291, P = 0.039). After adjusting for age, sex and presence of diabetes, IMT was independently associated with PWV (HR 2.110, 95% CI 1.036-4.298, P = 0.040). The risk of recurrent vascular access failure was higher in the high IMT group (HR 1.615, 95% CI 1.460-5.669, P = 0.034).

Conclusion: IMT was associated with PWV and recurrent access failure. Thus IMT may be suggested as a potential predictor of vascular access failure.

SUCCESSFUL THROMBOLYSIS OF AN ATRIAL TUNNELED DIALYSIS CATHETER AS A LAST RESORT VASCULAR ACCESS
Salah Saïd1, Najjar Mariem1, Meriem Mbarek1, Ilhem Ben Othman1, Imane Gorsane2, Yassine Khadhar2, Tasnim Ben Ayed3, Hayet Kaaroud1, Fethi Ben Hmida1, Jaleleddine Zidi2 and Ezzeddine Abderrahim1
1Charles Nicolle Hospital, Department of Internal Medicine A, Tunis, Tunisia, 2La Rabta Hospital, Department of Cardiac and Vascular surgery, Tunis, Tunisia and 3Charles Nicolle Hospital, Kidney Pathology Laboratory LR005P01, Tunis, Tunisia

Background and Aims: The prolonged survival of patients on dialysis has resulted in a higher frequency of complications and failure related to vascular access. As a result, the situation of depleted vasculature in hemodialysis is becoming increasingly prevalent. The use of an atrial tunneled dialysis catheter (ATDC) has been reported as an effective solution for vascular access in these patients, but limited data is available on the associated complications, particularly thrombosis.

Method: This study reports the experience of a single nephrology center in Tunis with thrombosis of an ATDC as a last resort vascular access for dialysis.

Results: A 32-year-old patient with undetermined tubulo-interstitial nephropathy receiving dialysis presented in November 2022 with depleted vasculature. An ATDC was inserted as a final solution for vascular access. One month later, dialysis could not be initiated through the ATDC. Catheter thrombosis was diagnosed as a guidewire was unable to pass through the catheter's lumen. The patient was successfully treated with thrombolysis using 50 mg of Alteplase, allowing dialysis to be resumed with a blood flow of 300 mL/min.

Conclusion: ATDC is a lifesaving and safe option for patients with depleted vasculature, with only 51 cases reported since 1999 [1]. The treatment of catheter thrombosis is not well defined, and to the best of our knowledge, no thrombolysis protocol has been established. This successful case may contribute to filling the knowledge gap in this field.

THE IMPACT OF COVID-19 PANDEMIC ON PSYCHOLOGICAL AND SOCIOECONOMIC WELL-BEING OF HEMODIALYSIS PATIENTS: AN ANALYTICAL CROSS-SECTIONAL STUDY
Jane Angele Pasamante
Makati Medical Center, Internal Medicine, Section of Nephrology, Makati, The Philippines

Background and Aims: This study aimed to determine and assess the prevalence of depression, anxiety, and stress of the COVID-19 pandemic among...
outpatient hemodialysis patients and the relationship to sociodemographic and clinical factors, and to assess the economic impact of the COVID-19 pandemic.

**Method:** In this analytical, cross-sectional study, purposive sampling was used and a total of 69 subjects were enrolled. Sociodemographic data were collected using researcher-administered questionnaires and recent laboratory parameters were collected by reviewing medical records. Patients completed 4 sets of questionnaires including Patient Health Questionnaire 9 (PHQ-9), Generalized Anxiety Disorder 7 (GAD-7), Perceived Stress Scale 4 (PSS-4), and CoRonavirus Health Impact Survey (CRISIS). Quantitative variables were presented using mean and standard deviation, median, and Interquartile Range (IQR). Qualitative variables were presented using frequency and percentages. Pearson's correlation was used to determine the relationship of laboratory parameters with anxiety, depression, and stress scores. The Chi-Square test was used to determine the relationship of sociodemographic profile with anxiety, depression, and stress scores. P values <0.05 were considered statistically significant.

**Results:** Our study showed that the prevalence of anxiety, depression, and stress were 39%, 16%, and 51% respectively. There was an association between age and stress level, with older subjects reporting higher stress scores. Hemoglobin levels had a weak negative correlation with anxiety, depression and stress. The distribution of anxiety scores was significantly different between patients with normal phosphorus levels and elevated phosphorus levels. Financial worries were less of a concern since almost two-thirds of our subjects were retired and unemployed.

**Conclusion:** Hemodialysis patients belong to high-risk populations with a high prevalence of psychological distress hence they are subjected to more severe psychological stress, depression, and anxiety. Our findings suggest that psychological intervention may be necessary for some patients during this pandemic.

**BLOOD UREA NITROGEN TO CREATININE RATIO IS ASSOCIATED WITH HIGH MORTALITY IN ELDERLY PATIENTS STARTING HEMODIALYSIS: A KSGN RETROSPECTIVE COHORT**

Daeseul Huh1, Keonhwa Kim1, Sang-Eun Kim1, Ji hyun Yang1, Kyu-Beck Lee1, Hyang Kim1 and Young Youl Hyun1

1 Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Internal Medicine, Seoul, Rep. of South Korea and 2 Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Hospital Medicine, Seoul, Rep. of South Korea

**Background and Aims:** Previous studies have shown that increased blood urea nitrogen to creatinine ratio (BCR) is a poor prognostic marker in patients with some chronic diseases or in the general population. However, the clinical implication of BCR in elderly dialysis patients is unknown. The purpose of
this study was to verify the association of BCR with the risk of death in elderly patients starting hemodialysis.

Method: The Korean Society of Geriatric Nephropathy Retrospective Cohort consists of patients who started maintenance hemodialysis from January 1, 2010 to December 31, 2017 at 17 nephrology centers in Korea. After excluding patients with malignancy or estimated glomerular filtration rate 30 ml/min/1.73 m2 or greater, we retrospectively analyzed 2183 patients. The main predictor was patients BCR at the time of hemodialysis initiation and subjects were divided into four groups according to their BCR quartile. The main outcome was all-cause mortality.

Results: During 7,545 person-years of follow-up, 1,382 (63.3%) patients died. Patients in the high BCR group died more (60.9%, 59.3%, 62.5% and 70.5% for the 1st to 4th BCR quartiles, respectively, P=0.001). In multivariable Cox proportional hazard model, BCR increase by one was associated with increased risk of death (HR 1.01; 95% CI, 1.01-1.02). This model was adjusted for age, sex, body mass index, cause of renal disease, hypertension, diabetes, ischemic heart disease, cerebrovascular disease, congestive heart failure, eGFR, hemoglobin, albumin, calcium and phosphorus. Compared to 3rd quartile of BCR group, 4th quartile group was associated with increased risk of death (HR; 1.30; 95% CI, 1.12-1.51).

Conclusion: High BCR is a predictor of high mortality in elderly patients starting hemodialysis. This result suggests that more attention should be paid to elderly patients starting hemodialysis with high BCR.

COVID-19 IN ELDERLY CHRONIC HEMODIALYSIS PATIENTS: PREDICTORS OF MORTALITY

Nada Sellami1, Wiem Belhaj1, S Agrebi1, M Khadhar1, T Ben Ayed1, R Lazzez1, S Bouassida1, S Jouini1, M Ounissi1, F Ben Hamida1,2, T Ben Abdallah1 and E Abderrahim1

1Charles Nicolle Hospital, Department of Internal Medicine “A”, Tunisia, 2La Marsa Hospital, Department of Nephrology, Tunisia, 3Hospital Emergency, Tunis and 4Charles Nicolle Hospital, Laboratory of Renal Pathology (LR05SP01), Tunisia

Background and Aims: Studies have shown that the incidence of severe COVID-19 pneumonia is higher in elderly patients and especially those with comorbidities including chronic kidney disease. The aim of our study was to determine risk factors for mortality in elderly chronic hemodialysis (HD) patients.

Method: We conducted a cross-sectional, observational, and analytical study, in the dialysis unit of the internal medicine department at Charles Nicolle Hospital over an 11-month period from September 2020 to August 2021. We studied the correlation between mortality and the different epidemiological, clinical and biological data via the SPSS software.

Results: We included 59 patients, with a mean age of 73 years [65-93] and a gender ratio of 1. All patients had confirmed COVID-19 infection, chronic kidney failure and required regular HD session at least 3 months. One on four patients had a coronary artery disease, 55% were diabetics and 72% had hypertension. From the 19 patients who underwent chest scan, 68% had severe lesions. Emergency HD had to be conducted for 25% of the patients, mainly because of hyperkalemia. At least one ongoing HD session was interrupted for neurologic, hemodynamic or respiratory instability in 26% of the patients. Mortality rate was 58%. Data that were associated with mortality in the univariate study were oxygen needs (p<0.001), COVID-19 infection severity (p=0.007), and interruption of HD session (p<0.003). Low blood pH levels and high pCO2 levels were also correlated to mortality (p=0.032 and p=0.020). Predictors of mortality in multivariate analysis were high oxygen needs (OR=1.368; 95% CI [1.081-1.732]; P=0.009), interruption of HD session (OR=1.426; 95% CI [1.070-1.846]; P=0.014) and severe form of COVID-19 infection (OR=1.770 95% CI [1.062-2.980]; P=0.029).

Conclusion: According to these results, high oxygen needs, severity of COVID-19 infection and interruption of HD session represented risk factors of death in elderly patients undergoing chronic hemodialysis. As highlighted in previous studies, mortality rate in COVID-19 seems to be higher among elderly patients. However, diabetes and cardiovascular diseases were not identified as predictors of mortality in this sample of patients.
SAFETY OF RAMADAN FASTING IN DIALYSIS PATIENTS: A TUNISIAN PROSPECTIVE MULTICENTER STUDY

Sirine Bchir1, Amel Ayed1, Nouha Ben Mahmoud1, Lazhar Jaballah1, Fadoua Hassine1, Sasssen Chouchen4, Samir Nouira3, Meriem Ben Salem1, Manel Ben Salah1, Hadj Brahim Mayssa2, Ahmed Latief1, Fawzi Hawala1, Mouna Hammouda1, Habib Skhiri1, Zohra Elati2 and Aloui Sabra1

1Faculty of medicine of Monastir, Monastir University, Departement of Nephrology-Transplantation and Dialysis- Fattouma Bourguiba University Hospital, Monastir, Tunisia, Tunisia, 2Faculty of medicine of Monastir, Monastir University, Departement of Nephrology and Dialysis- Taher Sfar University Hospital Mahdia, Tunisia, Tunisia, 3Biochemical Laboratory, Fattouma Bourguiba University Hospital, Monastir, Tunisia, 4Hematology Laboratory, Fattouma Bourguiba University Hospital, Monastir, Tunisia and 5Emergency Departement, Fattouma Bourguiba University Hospital, Monastir, Tunisia

Background and Aims: Hemodialysis patients are generally exempt from Ramadan Fasting (RF) because they are more vulnerable to the risk of malnutrition as well as fluid and electrolyte imbalance. In addition, many muslim hemodialysis patients feel the spiritual need to fast during Ramadan, even when they are not compelled to do so. Moreover, there are no medical recommendations that specify who should and should not fast. The aim of our study is to explore the experiences of Muslim Hemodialysis patients fasting Ramadan in Hemodialysis centers.

Method: This prospective multicenter study involved patients from eight different hemodialysis centers in Monastir and Mahdia cities. Biochemical, clinical parameters and bioimpedance monitoring were performed before, during and after Ramadan with a group of Fasting Ramadan patients (RFG) and a group of Ramadan non-fasting hemodialysis patients (RNFG). Patients in RFG did so as a personal choice and they wouldn’t skip fasting on dialysis days due to fear of the side effects of fasting. Oral consent was taken from all the patients included in the study.

Results: One hundred and four (104) patients were enrolled in this study. Among them, 44 were in the RFG, and the remaining sixty (60) patients were in the RNFG. The mean age of RFG and RNFG was 47.13 +/− 12 years and 54.7 +/− 15 years, respectively. 32 patients (52.3%) were males in RFG and 38 were males (63.3%) in RNFG.

In RFG, about 6.8% (n = 3) and 43.2% (n = 19) had diabetes and hypertension, respectively. The mean duration on hemodialysis was 7 +/− 6.27 years. There were no significant differences between RFG and RNFG except in diabetic and hypertension status. Comparing biological findings pre, during and post-fasting in RFG, no significant differences were noted in serum sodium (135.9 +/− 4; 135.8 +/− 2.5 and 136.3 +/− 2.4 mmol/l respectively) and there were no drop in serum albumin during fasting (40.4 +/− 3.4; 40.8 +/− 3.7 and 40.6 +/− 4.34 g/l respectively). However, mean serum potassium was higher during RF (5.59 +/− 0.8 ; 5.6 +/− 1 and 5.2 +/− 0.88 mmol/l respectively) and, mean serum Phosphorus was also higher during RF (1.54 +/− 0.57; 1.73 +/− 0.52 and 1.69 +/− 0.7 mmol/l respectively).

Furthermore, with bioimpedance monitoring, comparing pre, during and post Fasting, more fluid retention in patients was observed during fasting (51.67 +/− 7; 54.3 +/− 7, 4 and 53.2 +/− 6 % respectively). But the mean of the inter dialytic weight gain (IDWG) remained the same (2.57 +/− 0.8 ; 2.53 +/− 1.1192 Abstract
0.82 and 2.61 \( \pm \) 0.7 Kg respectively), and none presented with pulmonary oedema or other emergency that might need hospitalization. However, there was positive change to body composition between pre and during fasting, shown as lower body fat mass (FM) percentage during fasting (29.4 and 28.2\%) respectively and also, lower body mass index (BMI) (26.5 and 25.9 respectively).

Nevertheless, when comparing findings between RFG and RNFG, there was no significant difference in any parameters.

Conclusion: The overall conclusions suggest that fasting is relatively well tolerated by hemodialysis patients and does not affect the morbidity and mortality rates. However, careful monitoring of fluid balance, serum electrolytes, and albumin is advisable.

#5153
CHARACTERISTICS AND MORTALITY OF PATIENTS STARTING HAEMODIALYSIS IN A PORTUGUESE TERTIARY HOSPITAL: A DESCRIPTIVE ANALYSIS
Carolina Branco\(^1\), Claudia Costa\(^1\), Bernardo Marques Da Silva\(^1\), Nadiesda Peres\(^1\), Mariana Sant'ana\(^2\), José Agapito Fonseca\(^1\), Cristina Outerelo\(^1\), Cristina Resina\(^1\), José António Lopes\(^1\) and Joana Gameiro\(^1\)
\(^1\)Centro Hospitalar Universitário Lisboa Norte, Nephrology and Renal Transplantation, Lisboa, Portugal and \(^2\)Faculdade de Medicina de Lisboa, Lisboa, Portugal

Background and Aims: Portugal has one of the highest incidences and prevalence of end-stage kidney disease in Europe, with haemodialysis (HD) being the most common modality of renal replacement therapy. The aim of our study was to analyse a cohort of patients who started HD in a large tertiary care hospital in Lisbon and describe the evolution of the patient characteristics throughout the studied years.

Method: This study was a retrospective analysis of all adult individuals who started HD between January of 2014 and December of 2019 in tertiary care hospital in Lisbon. Data was attained from individual electronic clinical records. The primary outcome was mortality. Statistical significance was defined as a P-value lower than 0.05.

Results: We included 1122 patients (mean age 64.9 \( \pm \) 16.8 years, 21.2\% at least 80 years old; 60.9\% male and 79.7\% caucasian). At HD start, mean eGFR was 8.98 \( \pm \)5.66mL/min/1.73 m\(^2\) and the vascular access was a central venous catheter in 56.0\%, an arteriovenous fistula in 40.6\% and an arteriovenous graft in 3.4\%. The number of patients that started HD per year was variable between 169-204 and the percentage of elderly patients increased throughout the years. There was a trend of initiating dialysis with progressively lower eGFR. The percentage of patients with central venous catheter increased. In total 392 patients died (7.5\% within the first 90 days of starting HD). Mortality rate within the first 90 days and first year declined from 2015 to 2019. As expected mortality was higher in older patients (Fig. 1), as well as in patients that started HD with a central venous catheter (Fig. 2).

Conclusion: We describe a large cohort of Portuguese patients that started HD between 2014-2019 that correlates well with the available recent data from the national and european registries. There was a greater percentage of patients initiating HD by catheter, which was associated with higher mortality. Although, considering the increase in elderly patients starting HD, their underlying comorbidities might impair vascular access placement and also have an impact on mortality. Additionally, despite the increase in elderly patients, mortality within the first 90 days and first year declined, highlighting the quality of care provided, in addition to a better acknowledgment and referral to conservative care.

Improvements in Quality of Life (QoL) of Hemodialysis Patients After the Pandemia; It Is Not What It Seems to Be

Isabel Berdud-Godoy1, María Teresa Hernández2, Sofía Ortego3, Alicia Sobrino Pérez2, Abraham Rincon Bello4, Clarenicio Cebrián Andrade4, Kateryna Shkolenko3, Diana Samaniego3, Ramón Devesa Such3 and María Eva Baró Salvador1

1Fresenius Medical Care, Córdoba, Córdoba, Spain, 2Fresenius Medical Care, Cáceres, Cáceres, Spain, 3Fresenius Medical Care, Medical Department, Madrid, Spain and 4Fresenius Medical Care, Sevilla, Sevilla, Spain

Background and Aims: Patients on hemodialysis (HD), are a clinically vulnerable population. We analyzed changes in the results of the KDQOL™-36 questionnaire carried out in 2019 vs 2021, during Covid-19 pandemic. We have related the results to demographic and analytical parameters, BCM, modality and dose of dialysis, in addition to having suffered a COVID-19 infection.

Method: This is a retrospective, observational analysis performed in 47 clinics from Fresenius Medical Care (FMC) Spain. As part of our Healthcare Quality Improvement Program, HRQoL measurements were assessed using the KDQOL™-36 questionnaire. This questionnaire evaluates Physical and Mental Composite Scores (PCS and MCS, respectively) and three disease-specific scales: Effects, Burden and Symptoms dimensions (EKD, BKD, SKD). We focused our analysis in 1000 patients who completed both surveys in 2019 and 2021 in order to analyze differences. We compared results of both surveys by Wilcoxon test. Improvement between 2019 and 2021 was calculated for each QoL Score. We categorized patients based on QoL evolution (improvement vs worsening) and analyzed the relationship between QoL improvement and different variables by univariate and multivariate logistic regression. Non-normal variables were categorized.

Results: The results are presented in detail in the figures section.

Table 1: Comparison of results of different KDQOL-36 scales between 2019 and 2021. Median [Interquartile Range].

Conclusion: Except for the PCS, there were an improvement in QoL results in 2021 vs 2019. Women presented a worse evolution in EKD, MCS and SKD scores. In our study, having COVID-19 infection did not seem to be a factor associated with changes in quality-of-life in 2021. Patients on OL-HDF presented an improvement on the SKD scale compared to those treated with conventional therapy. Higher lean tissue index was related with improvement in PCS scale. Age was related with better EKD scale evolution as CCI above 5 was related with MSC Improvement. BKD scale evolution was related with HD vintage.

### Background and Aims:
Acute kidney injury (AKI) diagnosis, management, the optimal prescription and delivery of renal replacement therapy (RRT) standards for best practice are lacking. The aim of this study was to explore the clinical approach to AKI and RRT in a broad population of Brazilian nephrologists.

### Method:
A cross-sectional survey was distributed to all nephrologists from multiple centres of a Brazilian private hospital group. The responses of the participants on several aspects of AKI management and renal replacement therapy were analysed and detailed.

### Results:
97 (66%) nephrologists from 8 Brazilian states responded. 45% referred KDIGO 2 as the stage usually present at time of nephrologist consultation, and mean time for nephrology consultation after AKI diagnosis was 24-48h for 51% of answers. 85% reported creatinine as the only biomarker available for diagnosis, and only 24% reported any AKI alert system. Sepsis was reported as the most frequent etiology by 95%; kidney biopsy indication was considered in less than 10% of the evaluations by 94%. Fluid status assessment is described in Figure 1. The most common criteria for starting RRT was fluid overload (30%) followed by urine output reduction (26%), hyperkalemia (14%) and acidosis (17%). 62% of them usually use furosemide stress test before RRT indication. Seventy-seven percent of participants said that never use peritoneal dialysis in AKI patients, although its available for 44% of responders. Hypotension was the most frequent RRT complication for 91% responders, followed by coagulation of the system for 42% and catheter dysfunction for 33%. CRRT was available for 92% of participants and for 88% this is the RRT for patients using vasoactive drugs. 77% usually use regional anticoagulation with citrate. The most common starting dose is 26 to 30ml/Kg/h and the net ultrafiltration rate is 1.01-1.75 ml/Kg/h. There is no weaning protocol of RRT for 81%, but 90% use the urine output as a weaning tool. Thirty- nine percent said that RRT patients’ mortality stayed between 20 to 50%, and 36% had no information about mortality.

### Conclusion:
In our survey, Nephrology consultation occurred after 24h and at KDIGO 2 stage. Early recognition of AKI is impeded by the use of serum creatinine as the only biomarker and the unavailability of AKI alerts. Fluid overload is the main reason for indicating RRT and nephrologists have expanded the use of non-invasive fluid status assessment methods others than physical examination. CRRT is the method of choice for unstable patients in this sample from private medical facilities, where almost all responders have access to CRRT. Effluent doses and net ultrafiltration rate were in accordance with the established in literature. Optimal timing for discontinuing RRT is still defined according to the physician's discretion. Standardization of AKI management and continuing education seem to be a fundamental aspect to anticipate the diagnosis, improve the therapeutic approach and bring better results for AKI patients.
Conclusion: After the massive vaccination, the higher number of patients and without memory bias are needed to prove an incidence of post-COVID-19 syndrome is due to the vaccination. Even so, more studies with a higher number of patients and without memory bias are needed to prove a lower incidence of this syndrome after the massive vaccination. Therefore, the higher number of patients and without memory bias are needed to prove a lower incidence of this syndrome after the massive vaccination.
Abstract

Objective: To study the mortality risk among incident hemodialysis (HD) patients in the presence of intradialytic exercise (IDE).

Method: A single-center, prospective study in adult HD patients eligible for IDE (cycling 3 times a week) was performed. After 1 year of IDE introduction, patients were followed up for up to 3 years. Three groups were created based on the IDE minutes per week: no exercise (patients who refused IDE), low load (≤87 min/week), and high load (>87 min/week). Kaplan-Meier models (unadjusted analysis) and Cox proportional hazard models (adjusted for age, dialysis experience, vascular access, comorbidity index, CVD, muscle tissue, overhydration, and hospitalizations) were used with a non-exercise group as a reference. In addition, a sub-analysis was conducted, limited to IDE participants, with exposure as a continuous variable.

Results: 106 patients (no exercise: 58; low exercise: 26; high exercise: 22) were followed for an average of 24.5 months. Uncorrected mortality differed between the three groups: (no exercise: 24.1%; low load: 23.0%; high load: 9.0%; p < 0.01). In the adjusted analysis, the high load group had a lower risk of mortality than the no exercise group (HR = 0.42, 95% CI 0.23–0.76, p < 0.05), while in the low load group this was not observed (HR = 1.07, 95% CI 0.66–1.52, p = 0.568). In addition, mortality risk decreased for every 55 minutes of exercise per week in unadjusted (HR = 0.46, 95% CI 0.29–0.76, p = 0.01) and adjusted analyzes (HR = 0.54, 95% CI 0.32–0.91, p < 0.05).

Conclusion: Our findings show that IDE is associated with a reduced risk of mortality in HD patients, but a significant amount of exercise is required. Thus,

**Figure 1:** Graph of overall survival probabilities over time. Shaded areas represent the 95% confidence interval for survival estimates.
patients who achieve low load doses may require non-clinical approaches to PA in addition to IDE. These findings complement those of earlier studies and highlight the need for a tailored approach to the exercise.

#6715
COGNITIVE IMPAIRMENT IS ASSOCIATED WITH INCREASED MORTALITY IN HEMODIALYSIS PATIENTS
Evgeniy Shcherbakov¹ and Mikhail Pyatchenkov²
¹Military-medical Academy, Department of Nephrology and Blood Purification, Saint Petersburg, Russia and ²Military-medical Academy, Department of Nephrology and Blood Purification, Saint Petersburg, Russia

Background and Aims: Patients on dialysis are at substantially higher risk for developing cognitive impairment compared with the general population. At the same time cognitive impairment is a strong and independent risk factor for all-cause mortality. Given that the approaches used to access the prevalence of cognitive dysfunction widely vary in different patient populations, their true burden in hemodialysis patients remains poorly understood. The aim of our study was to determine the association between cognitive impairment and overall survival and mortality in patients undergoing hemodialysis treatment.

Method: A total of 69 chronic hemodialysis patients (47 men and 22 women) were included. The median age of patients was 61 [47-69] years. The median duration of hemodialysis treatment was 32 [21-72] months. The study of cognitive status was conducted using the Montreal Cognitive Assessment (MoCA) questionnaire. The test results are between 0 and 30 points. A score of 26 points or more is considered the norm, less than 26 indicates the presence of cognitive impairment. The end point was a fatal outcome from acute pathology or progression of a chronic disease. The analysis of survival and mortality was evaluated using survival tables, the construction of Kaplan-Mayer curves with the Mantel-Cox log-rank criterion. The risks of the influence of cognitive impairment on mortality were assessed using Cox regression.

Results: During the 24-month follow-up period, 23 patients died. Structure of mortality over the observation period: acute coronary syndrome – 6 (26 %), COVID-19 – 6 (26 %), acute cerebrovascular accident – 2 (9%), thromboembolic complications – 3 (13%), another causes – 6 (26 %). In patients with cognitive impairment on hemodialysis, the average survival value was 16.33 months ± 1.70 months [CI 95% 12.99-19.66] and 20.48 months±1.32 months [CI 95% 17.88-23.07] in patients without cognitive impairment. In patients with cognitive impairment the average survival value was 16.33 months ± 1.70 months [CI 95% 12.99-19.66] and 20.48 months±1.32 months [CI 95% 17.88-23.07] in patients without cognitive impairment. According to the Mantel-Cox log-rank criterion, there was a statistically significant decrease in overall survival in patients with cognitive impairment, \( P = .02 \). The mortality rate of dialysis patients with cognitive impairment was 51%, without cognitive impairment – 19%. Relative risk of death in the group of patients with cognitive impairment using Cox regression: Hazard ratio (HR) = 2.90 [95% CI 1.11-7.37, \( P = .03 \)].

Conclusion: Our results support the notion that cognitive impairment may be an independent predictor of all-cause mortality in hemodialysis patients. There are limitations on the sample size of patients in our study. Further larger-scale observations a large cohort of patients are required.

Figure 1: Kaplan-Mayer curves characterizing overall survival depending on the presence or absence of cognitive disorders.

DEPENDENCE IN THE ELDERLY PATIENT ON HEMODIALYSIS

Monica Pereira¹, Paula Manso¹, Marina Burgos¹, Damian Carneiro¹, Sebastián Mas¹, Emilio Gonzalez-Parra³, Maria Dolores Arenas¹ and Maria Luz Sánchez-Tocino¹

¹Fundación Renal, Madrid, Spain, ²CIBERDEM / IIS-FJD, Madrid, Spain and ³Instituto de Investigación Sanitaria Fundación Jimenez Diaz, Madrid, Spain

Background and Aims: Frailty constitutes a syndrome, characterized by loss of lean body mass (sarcopenia), weakness, and decreased resistance to physical exercise, which leads to decreased activity and a poor response to stress. Reduced activity, in turn, worsens sarcopenia and weakness, leading to a vicious cycle toward functional decline and increased risk of death. Frail patients starting HD may lose independence, as their functional capacity deteriorates, with increased frailty and sarcopenia, especially in the elderly.

Aims: Observe the clinical differences in elderly patients on hemodialysis depending on whether they are dependent or not and observe if dependence has an impact on the dialysis regimen used.

Method: Observational descriptive study for 1 year in patients of the chronic hemodialysis program of four out-of-hospital centers and a hospital unit of the Fundación Renal Íñigo Álvarez de Toledo (Spain). Of the total number of patients receiving dialysis in the units, 107 over 75 years of age, who had been in the program for more than 3 months and who had signed the informed consent, were included in the study.

The variables considered for the study were: age, sex, height, weight, and body mass index (BMI), etiology of kidney disease, time on hemodialysis, residual diuresis > 500 mL/min, and type of vascular access. In relation to the hemodialysis regimen, the duration variables were collected in hours of the HD session at the beginning of the program and at the time of the study, weekly hours and days per week

Analytically determined: albumin, total iron binding capacity (TIBC) and creatinine. In addition, the measure of dialysis efficacy was established by eKt/V

Results: Association between dependency and the rest of the qualitative variables. Data expressed n(%) or mean ± SD.

Conclusion: Dependent patients have lower residual renal function, greater comorbidity, less ability to walk, and therefore need transportation to go to dialysis, live in residences, and are extremely tired at the end of dialysis.

Implementation of alternative therapy practices does not influence dietary compliance in chronic kidney disease: a cross-sectional study

Dimitra Prokopiou, Themistoklis Defteros, Pinelopi Papadopoulou, Christina Pouliantii, Theodoros Eleftheriadis, Ioannis Stefanidis

University of Thessaly, Nephrology, Larissa, Greece

Background and Aims: Implementation of alternative therapies is a common practice in patients with chronic disease. Frequency in different countries is varying, highly dependent on local cultural habits. Furthermore, alternative therapy, especially if taken seriously, might be associated with reduced compliance to conventional interventions. Chronic kidney disease (CKD) is a progressive chronic illness with a really high mortality, which ends up with renal replacement treatment. In CKD certain dietary restrictions are central part of conventional treatment. The scope of the presented study was to determine prevalence of self implementation of alternative therapies and its relationship with compliance to dietary restrictions in CKD patients in Greece. Respectively epidemiological data are still totally missing.

Method: Consecutive patients of the Outpatient Nephrology Wards and all patients of the Peritoneal Dialysis (PD) and Haemodialysis (HD) Units of the University Hospital of Larissa, the General Hospital of Veria and the University Hospital Attikon in Athens (Greece) were studied after informed consent from June to December 2019. The international Complementary and Alternative Medicine questionnaire (I-CAM-Q), was applied. The questionnaire registers all visits to complementary or alternative health-care providers, the respective treatments, the use of herbs, of dietary supplements, and self-help practices. Patients’ 24h recollection data were used to calculate dietary intake of protein, sodium, potassium and phosphorus. Albumin, phosphate, sodium, potassium, creatinine and urea were determined with routine methods in the central Laboratory of the University Hospital of Larissa.

Results: Overall 261 patients (165 males, aged 66.1 ± 13 years) with CKD were included. Among them 102 were on chronic haemodialysis and 59 on peritoneal dialysis treatment. The prevalence of alternative treatment practices was overall 45%, significantly higher in female patients (OR 1.494, ci 1.085-2.057, $P = 0.015$). The frequency in PD patients and in CKD patients was significantly higher than in HD patients (PD 69.5%, CKD 55% and HD 21.6%; $P < 0.01$). There was no significant variation due to profession or education. The prayers and confession (31.1%) as well as the use of herbs (25.3%) were the most frequent alternative practices applied. In HD prayers (prevalence 8.9%) and the use of herbs (8.9%) are less frequently practiced than in the other groups. The dietary compliance was for phosphorus about 24% and when all relevant diet parameters were considered 18%. Compliance to dietary restrictions was better in females ($P = .024$) but was independent of the patient’s profession ($P = .42$) and educational status ($P = .89$). No significant influence of the alternative treatment practices application was determined on the compliance to diet of either CKD, PD or HD patients.

Conclusion: The autonomous implementation of alternative medical and other treatment and self-help practices is common among patients with CKD with a predominance of females. In Greece the most commonly applied practices are herbs and prayers or the confession. There is overall a lower prevalence of alternative practices in HD patients than CKD and PD patients. The initial hypothesis, namely that alternative therapy implementation might combine with reduced compliance of patients to conventional interventions was not confirmed at least as far as the dietary restrictions prescribed for CKD patients are concerned. The role alternative treatment practices in CKD and its relationship to the patients’ physical and mental health deserves further investigation.

Epidemiological and clinical characteristics of migrants on chronic hemodialysis treatment

Gaetano Alfano, Francesco Fontana, Riccardo Magistroni, Gabriele Donati

Modena, Italy

Background and Aims: The rate of migrants with end-stage kidney disease is rising in Italy. Migrants often present to nephrologists with advanced kidney disease, a condition that limits the choice to perform a diagnosis and prevent the progression of the disease. Low literacy, language barriers, lack of medical insurance, illiteracy and cultural diversity are the main factors limiting the referral to physicians. Data about the prevalence and clinical characteristics of migrants in dialysis units are scarce in the literature. Our study aimed to evaluate and characterize the epidemiological profile of migrants on chronic hemodialysis (HD) treatment. Data about demographics, clinical characteristics health-related quality of life (HRQoL) were compared with the Italian population.

Method: A retrospective cross-sectional observational study was conducted on patients who underwent HD at the University Hospital of Modena from December 2021 to August 2022. All patients on chronic HD treatment aged > 18 years were enrolled in the study. Data were collected from electronic health databases and interviews with a selected number of patients. HRQoL was evaluated by “EQ-5D” questionnaire. Overall, it ranged between a score from level 5 (no problem) to 25 (extreme problems). A scale (EQ VAS), numbered from 0 (worst imaginable health) to 100 (best imaginable health) was used to assess global assessment of own health. Patients have been subdivided based on their origin into ‘migrants’ and ‘non-migrants’ (or Italians). According to the International Organization for Migrations (IOM), we considered migrants all patients that were born in a foreign country and came to Italy for work, family reunification, economic or political reasons.

Results: In our hemodialysis center, 302 patients underwent hemodialysis for kidney failure. Migrants accounted for 18.2% (n. 55) of the HD population. They moved to Italy from Africa (62%), Europe (20%), Asia (16%) and Latin America (2%) for seeking work (84.3%) and family reconciliation (15.7%). A consistent percentage of migrants (37.5%) crossed the national border as undocumented migrants. Migrants started hemodialysis at a younger age than non-migrants (48.1 [IQR, 39.7-56.7] vs 70.7 [IQR, 70.7-78.5]) years ($P = .001$) (Fig. 1). Most of them were male (69%). Migrant starter HD after 12.3 (IQR 6.5-20) years from their arrival in Italy. The age of migrants varied according to the geographic area: Subsaharian Africa (44.7 years), Asia (46 years), Europe (53.9 years) and northern Africa (54.5 years), although there was no statistically significant difference between groups ($P = .67$). The etiology of kidney disease was unknown in 40% of patients. Most of the patients (54.5%) started HD with a central vein catheter (CVC) and 33% of them were not referred to a nephrologist before HD. After a follow-up of 1.8 years, the rate of CVC decreased to 26.3%. Only 14.5% of the interviewed patients declared to be informed about home dialysis. Although, 87.2% of the patients were potentially eligible for kidney transplantation (age criteria) only a few of them (18.7%) was active on the waiting list.

Migrants have a better perception of health-related quality of life than non-migrants. In the migrants and non-migrant groups, median “EQ-5D” score was 5 (IQR, 5-6) and 7 (IQR, 5-10), respectively ($p = <.0001$). Global health assessment in migrants and non-migrant accounted for 90 (IQR, 80-91.5) and 80 (IQR, 70-90), respectively ($P = .028$). It is worth noting that these differences became not statistically significant when EQ-5D ($P = .45$) score and EQ VAS scale ($P = .52$) were adjusted for the age of participants.

Conclusion: Migrants were a consistent percentage of patients in our Dialysis Unit. This group of patients was formed by young people often unaware of their kidney disease. Late referral to the nephrologist had a profound implication on vascular access for HD. The language barrier and cultural diversity were the major limitations to entry into the kidney transplant waiting list.
COMPARISON OF TRACE ELEMENT CONCENTRATIONS IN PREDIALYSIS, HEMODIALYSIS AND PERITONEAL DIALYSIS PATIENTS

Suleyman Koz¹, Esin Oğuz² and Cagla Sayın³

¹Sivas Cumhuriyet University Faculty of Medicine, Nephrology, Turkey, ²Sivas Cumhuriyet University Faculty of Medicine, Internal Medicine, Sivas, Turkey and ³Sivas Cumhuriyet University Faculty of Medicine, Internal Medicine, Turkey

Background and Aims: Regulation of many trace elements (TE) is critically dependent on kidney functions. Dialysis modality, duration of dialysis, equipment, purity of water and nutrition also impacts TE balance. There are inadequate data on comparison of TE in patients with different stages of kidney disease.

We aimed to compare TE levels in a restricted geographical area across a wide range of glomerular filtration rate (GFR) including end stage kidney disease. We assumed that this kind of design might be beneficial for understanding TE balance and impact of dialysis.

Method: Hemodialysis (HD), peritoneal dialysis (PD) and chronic kidney disease (CKD) patients with reduced GFR were included in this cross-sectional study. A sample of plasma was analyzed by inductively coupled plasma mass spectrometry (ICP-MS) (Thermo Scientific™ iCAP Q ICP-MS, USA). Sensitivity was on the order of ppb (μg/L). A control group (CG) with glomerular filtration rate ≥ 90 ml/min were used for comparison of plasma levels of TE.

Results: Results of TE are presented in the Table 1. Significant number of both patients and controls lack a valid TE measurement because of the concentrations below limit of the detection (LoD). Copper, in CKD patients, is negatively correlated with hospitalization within the last six months (r = -0.315, p= 0.005).

Conclusion: Our data suggest that TE levels except Zn and Mn deviate from that of CG in a statistically significant manner in renal patients. Existing data on TE in renal patients are inconsistent and there is some confusion. Similarly, our results are consistent with some data and conflicting with others. In future studies, this confusion could be eliminated by evaluating each trace element separately and minimizing methodological problems.

(This study is realized with support of Cumhuriyet University CUBAP)
Background & aims: The study recruited 202 eligible ESRD patients undergoing haemodialysis. Baseline characteristics of the study participants with and without Sudden Cardiac Arrest (SCA) were recorded using self-reported questionnaires. SCA and SCD events were identified by reviewing medical records and death certificates. Results: Out of 202 patients, 37 (18.3%) suffered from the episode of SCA, 18 (48.6%) of which succumbed to death. ESRD patients who endured SCA were statistically older in comparison with their non-SCA counterparts (58.2 ± 11.4 vs. 52.3 ± 9.3 years, P < 0.001). The HTN (67.6% versus 64.8%, P = 0.01), DM (62.2% versus 59.4%, P = 0.004), CAD (45.9% versus 41.8%, P = 0.001) and Congestive Heart Failure (CHF) (35.1% versus 34.5%, P = 0.002) were significantly prevalent in ESRD cohort with SCA in contrast to non-SCA. We also found LVH (62.2% versus 48.5%, P < 0.001), ventricular tachycardia (51.4% versus 30.9%, P < 0.001) and ventricular fibrillation/flutter (56.8% versus 25.5%, P < 0.001) to be statistically higher in ESRD patients on haemodialysis with SCA event. Through multivariate logistic regression analysis, we evidenced hypokalemia (OR 1.565, CI 1.469–2.342, P < 0.001); LVH (OR 1.861, CI 1.392–1.953, P < 0.001); CAD (OR 1.253, CI 1.012 – 1.386, P < 0.001); and ventricular fibrillation/flutter (OR = 0.547, CI 0.518 – 0.773, P < 0.001) to be significantly and independently associated with SCD in ESRD patients on haemodialysis.

Conclusion: The prevalence of SCD among ESRD patients on haemodialysis with SCA episode is very high. CAD and ventricular tachyarrhythmias were statistically significant among ESRD patients on haemodialysis with SCA in comparison with non-SCA and were independently associated with the prevalence of in-patient SCD among ESRD patients on haemodialysis.

INCIDENCE AND RISK FACTORS OF SUDDEN CARDIAC DEATH IN END STAGE RENAL DISEASE PATIENTS UNDERGOING HAEMODIALYSIS: A RETROSPECTIVE STUDY
Muhammad Tassaduq Khan
Dow University Hospital, Renal Transplant Unit, Karachi, Pakistan

Background & aims: End Stage Renal Disease (ESRD) patients undergoing haemodialysis are prone to suffer from Sudden Cardiac Death (SCD). The present study was sought to evaluate the incidence and risk factors of SCD in ESRD patients on haemodialysis in Pakistani population.

Methods: The study recruited 202 eligible ESRD patients undergoing haemodialysis. Baseline characteristics of the study participants with and without Sudden Cardiac Arrest (SCA) were recorded using self-reported questionnaires. SCA and SCD events were identified by reviewing medical records and death certificates.

Results: Out of 202 patients, 37 (18.3%) suffered from the episode of SCA, 18 (48.6%) of which succumbed to death. ESRD patients who endured SCA were statistically older in comparison with their non-SCA counterparts (58.2 ± 11.4 vs. 52.3 ± 9.3 years, P < 0.001). The HTN (67.6% versus 64.8%, P = 0.001), DM (62.2% versus 59.4%, P = 0.004), CAD (45.9% versus 41.8%, P = 0.001) and Congestive Heart Failure (CHF) (35.1% versus 34.5%, P = 0.002) were significantly prevalent in ESRD cohort with SCA in contrast to non-SCA. We also found LVH (62.2% versus 48.5%, P < 0.001), ventricular tachycardia (51.4% versus 30.9%, P < 0.001) and ventricular fibrillation/flutter (56.8% versus 25.5%, P < 0.001) to be statistically higher in ESRD patients on haemodialysis with SCA event. Through multivariate logistic regression analysis, we evidenced hypokalemia (OR = 1.565, CI 1.469 – 2.342, P < 0.001); LVH (OR 1.861, CI 1.392 – 1.953, P < 0.001); CAD (OR 1.253, CI 1.012 – 1.386, P < 0.001); and ventricular fibrillation/flutter (OR = 0.547, CI 0.518 – 0.773, P < 0.001) to be significantly and independently associated with SCD in ESRD patients on haemodialysis.

Conclusion: The prevalence of SCD among ESRD patients on haemodialysis with SCA episode is very high. CAD and ventricular tachyarrhythmias were statistically significant among ESRD patients on haemodialysis with SCA in comparison with non-SCA and were independently associated with the prevalence of in-patient SCD among ESRD patients on haemodialysis.

**IS THE NEUTROPHIL/LYMPHOCYTE RATIO USEFUL IN PREDICTING THE OCCURRENCE OF DEPRESSION IN CHRONIC HEMODIALYSIS PATIENTS?**

Imane Shabi\(^1\), Mariam Chettati\(^2\), Wafaa Fadili\(^3\) and Inass Laoud\(^4\)

\(^1\)University Hospital Mohammed VI, Marrakech, Morocco, Nephrology Department, Marrakech, Morocco and \(^2\)University Hospital Mohammed VI, Marrakech, Morocco, Nephrology Department, Morocco

**Background and Aims:** Depression is one of the most described psychiatric disorders in chronic hemodialysis patients. Previous studies have shown that the chronic inflammatory state is involved in the progression of depressive symptoms. The neutrophil/lymphocyte ratio (NLR) is an inexpensive and easily measured inflammatory marker. To date, the association between NLR and depression in this population in Morocco has never been described.

**Method:** In this multicenter cross-sectional study, we included a population of chronic hemodialysis patients over a period of 3 months (September-December 2023). The Patient Health Questionnaire-9 (PHQ-9) translated into Arabic (validated version) was used to assess depressive symptoms. NLR was calculated as the ratio of neutrophils to lymphocytes. An N/L ratio greater than 2.5 was considered high. We also used the patients' medical records to collect data on their biological tests and medical history.

**Results:** A total of 69 patients with a M/F sex ratio 1.2. The mean duration of HD was 7 ± 3.5 years, with a mean age of 53 ± 13.2 years. 28% were diabetic and 32% hypertensive. Depressive symptoms were detected in 20% of the 69 patients, and 72% of our patients had an NLR >2.5. In univariate analysis, PHQ-9 scores were positively correlated with NLR and negatively correlated with albumin. There was no correlation between PHQ-9 score and sex, age, duration of dialysis, diabetes, hypertension, ferritin. NLR was a significant predictor of mild (p = 0.06) and moderate or moderately severe (p = 0.04)

Efficacy of Ablation of Parathyroid Autografts for Recurrent Hyperparathyroidism After Total Parathyroidectomy and Deltoid Auto Transplantation

Julia G Andres, Guanqi Hang, Sum Leong, Chow Wei Too, Jiunn Wong

**Background and Aims:** TPDI is the treatment of choice for patients with severe hyperparathyroidism who have failed medical therapy in our centre. The auto-transplantation of parathyroid tissue in the deltoid reduces the risk of permanent hypoparathyroidism. However, there is a risk of recurrent hyperparathyroidism from the implanted parathyroid tissue. Traditionally, these autografts are removed surgically in the event of recurrent hyperparathyroidism exposing the patients to the risk of permanent hypoparathyroidism. We attempted radiologically guided ablation of the implanted tissue to allow near but not complete ablation of the tissue. We aim to report our experience in using this technique to treat patients with recurrent hyperparathyroidism following TPDI.

**Method:** This is a single centre retrospective study of 9 patients who are on regular dialysis and underwent ablation of their deltoid parathyroid implants at Singapore General Hospital between May 2020 to July 2022. Baseline demographic data, as well as biochemical results including intact parathyroid hormone (iPTH), serum calcium, phosphorus and alkaline phosphatase (ALP) levels were retrieved from electronic medical records and analysed. We define success of the procedure as achieving 2 out of the following 3 criteria: 1. >50% drop in iPTH level at 3 months, ii. correction of hypercalcemia at 3 months, iii. off calcimimetic at 3 months

**Results:** A total of 9 patients underwent ablation of their parathyroid deltoid implants, of which 8 (89%) had thermal ablation and 1 (11%) had cryoablation. 1 patient required a repeat procedure within 3 months as only 50% of the implanted tissue was targeted instead of the intended 80% and another patient had a repeat procedure >3 month after initial unsuccessful procedure. The median age of patients undergoing this procedure was 60 years (IQR 60, 66) and majority were female (5/9, 55.5%). 8 out of 9 patients were on haemodialysis. 7 out of 9 patients (78%) had a successful procedure based on our definition. 6 patients (67%) had a >50% reduction of iPTH at 3 month, 6 patients (67%) were off calcimimetic at 3 months and out of the 5 patients who were hypercalcaemic pre procedure, 4(80%) patients had normalisation of hypercalcemia at 3 months. 3 patients (33%) had iPTH < 2x upper limit of normal with only 1 out of the 3 patient requiring high dose oral calcium replacement at 3 months.

Pre ablation levels of PTH decreased from 191.87 ± 93.52 pmol/L to 98.77 ± 111.007 pmol/L (P = 0.773) 1 day after ablation and 92.450 ± 70.235 pmol/L (P = 0.0450) at 1 month and 91.25 ± 81.25 (P = 0.024) pmol/L at 3 months. Serum calcium levels decreased from 2.48 mmol/L ± 0.286 pre ablation to 2.11 mmol/L ± 0.322 1 day post ablation (P = 0.007) and remained 2.28 mmol/L ± 0.403 (P = 0.122) at 3 months post ablation. Serum ALP levels decreased from 478 ± 292.00 pre ablation to 238 ± 157 at 3 months post ablation.

There were no re-admissions and no immediate post procedure complications in all patients. 4 out of 9 patients (44%) required intravenous calcium replacement post- procedure during the same admission.

Limitations of this study are the relatively short follow-up duration and the small number of patients. 2 out of the 9 patients were lost to follow up at 3 months.

**Conclusion:** Ablation of deltoid parathyroid autografts may be a safe and effective minimally invasive procedure to manage recurrent hyperparathyroidism and minimising the risk of permanent hypoparathyroidism. However, further studies with larger sample sizes and longer follow up duration would be prudent to confirm our findings

Scratching the Surface? A Longitudinal Observational Study on Pruritus and its Current Treatment in Incident Dialysis Patients

Thomas Sebastiaan van Lieshout1,2, Violette de Ruiter1, Sanne de Lange3, Essme Dreihuis1,2, Robin Vernooij3,4, Thomas Rustemeeyer1, Alferco C. Abrahams1, Brigit Van Jaarsveld1,6,7

1Amsterdam UMC location Vrije Universiteit Amsterdam, Department of Nephrology, Amsterdam, The Netherlands, 2North West Clinic, Department of Internal Medicine, Alkmaar, Netherlands, 3University Medical Center Utrecht, Department of Nephrology and Hypertension, Utrecht, Netherlands, 4University Medical Center Utrecht, Julius Center for Health Sciences and Primary Care, Utrecht, Netherlands, 5Amsterdam UMC location AMC, Department of Dermatology, Amsterdam, Netherlands, 6Diapriva Dialysis Center, Amsterdam, Netherlands and 7Amsterdam Cardiovascular Sciences, Diabetes and Metabolism, Amsterdam, Netherlands

**Background and Aims:** Chronic kidney disease-associated pruritus (CKD-p) is a common condition in dialysis patients. It is associated with impaired health-related quality of life (HRQoL) and sleep disturbances. The pathophysiology remains unclear resulting in limited treatment options and lack of treatment guidelines. The exact course of CKD-p after dialysis initiation has not been identified nor the state of current medical treatment. Therefore, the aim of this study was to assess presence and severity of CKD-p during the first year of dialysis, and to assess how it is currently medically managed.

**Method:** Data were used from the ongoing multicentre, prospective, observational Dutch nOcturnal and hoME dialysis Study To Improve Clinical Outcomes (DOMESTICO). This study longitudinally compares HRQoL between different dialysis modalities. Incident dialysis patients (> 18 years) were included, if they completed a HRQoL questionnaire around initiation. Pruritus was assessed using the Dialysis Symptom Index (DSI), using a point Likert scale. Medication data were retrieved from electronic patient files. Outcome parameters were prevalence, severity of pruritus and the use of antipruritic medication, both systemic and topical, all measured at dialysis initiation and after 3.6 and 12 months. The association between pruritus and treatment was studied using logistic regression analysis and adjusted for potential confounders.

Association Between Physical Activity Level Questionnaires and Daily Step Counts in Patients on Hemodialysis

Maycon Moura Reboredo1, Bárbara Alvarenga1, Luciana de Jesus1, Gabriela Paticcio1, Carlos Miguel Da Silva1, Amanda Amorim1, Camila de Souza1, Eva Segura-Ortí2, Bruno Pinheiro1, Leda Lucinda1,2

1Federal University of Juiz de Fora, Juiz de Fora, Brazil, 2Universidade Cardenal Herrera-CEU, Valencia, Spain and 3Barbacena School of Medicine, Barbacena, Brazil

**Background and Aims:** In patients on hemodialysis, sedentary lifestyle is high and prevalent and associated with a worse health-related quality of life (HRQoL) and disturbed sleep. The physical activity level of these patients can be confirmed by assessing the physical activity level (PAL) evaluated by accelerometers and questionnaires. Considering that the PAL questionnaires are quick to perform and inexpensive, the aim of this study was to evaluate the association of three PAL questionnaires with daily step counts measured by an accelerometer in patients on hemodialysis.

**Method:** A cross-sectional study was conducted with patients aged ≥18 years on regular dialysis treatment for at least three months. Patients were excluded if presented severe and unstable comorbidities, psychiatric or cognitive disorders, and hospitalization in the past three months. The daily step counts were recorded in the ActiGraph accelerometer (wGT3X-BT) during seven days, and analyzed by excluding the first and last day of recording and calculating the mean among the valid days (≥ 8 hours of wear time). Subsequently, the Human Activity Profile (HAP) questionnaire, the International Physical Activity Questionnaire (IPAQ) and the physical functioning domain of the 36-Item Short Form Survey (PF SF-36) were applied. The normality of the data was analyzed using the Shapiro–Wilk test. The associations between each PAL questionnaire score and daily step counts were tested using Spearman’s correlation coefficients. Three, three linear regression models were constructed with daily step counts as the dependent variable and PAL questionnaire score and potential confounders (age, gender, educational level, time on dialysis, hemoglobin, and body mass index) as independent variables. A p value < 0.05 was considered as statistically significant.

**Results:** This study included 105 patients (59.2 ± 12.5 years, 60.0% male). Daily step counts correlated significantly with the questionnaires scores (HAP, ρ = 0.552, p < 0.001; IPAQ, ρ = 0.386, p < 0.001; PF SF-36, ρ = 0.337, p < 0.001). After adjusting for potential confounders, the multiple linear regression models showed an association between daily step counts with the HAP questionnaire score (R² = 0.31; adjusted R² = 0.26; p < 0.001) and PF SF-36 score (R² = 0.23; adjusted R² = 0.18; p < 0.001).

**Conclusion:** The PAL questionnaires were associated with daily step counts measured by an accelerometer in patients on hemodialysis. However, our results suggest that the HAP was the best questionnaire to evaluate PAL in these patients.
Results: A total of 643 patients were included, 70.8% started with hemodialysis and 29.2% with peritoneal dialysis. The mean (SD) age was 64.0 years (13.8) and 68.3% were men. At dialysis initiation 53.5% of all patients suffered from pruritus with a fluctuation in prevalence following the first year of dialysis (Fig. 1). During the first year 35.7% of the patients had persistent itching, 35.5% had fluctuating itching and 28.8% never experienced itching. There was a small increase in number of patients without itching at 3 months followed by an increase in number of patients with ‘quite some itch’ to ‘severe itch’ over the next months (Fig. 2). At 6 months after start dialysis 10.8% of the dialysis patients received topical antipruritic treatment, 17.2% received systemic antipruritic treatment and 3.3% received both topical and systemic treatment. The majority of patients with topical antipruritic treatment received emollients (58.9%) followed by cutaneous steroids (37.6%). Systemic steroids were the most used systemic antipruritic treatment (58.7%), followed by antihistamines (20.4%) and gabapentinoids (17.4%). Patients treated with topical agents at 6 months showed an odds ratio of 3.48 (95% CI: 1.11 – 10.91) on severe itching compared to patients without treatment. Furthermore, patients with systemic antipruritic treatment and with both systemic and topical treatment showed an odds ratio of 1.40 (95% CI: 0.48 – 4.03) and 1.52 (95% CI: 0.41 – 5.70) compared to patients without treatment respectively.

Conclusion: CKD-aP is highly prevalent in incident dialysis patients. The presence of CKD-aP is fluctuating during the first year of dialysis, with a third of patients experiencing intermittent itching. Starting dialysis may have a small beneficial effect on presence and severity of CKD-aP, but this is lost over time with moderate to severe CKD-aP increasing over the following months. Approximately a third of the patients received treatment for CKD-aP, predominantly as systemic treatment. The use of topical antipruritic treatment is associated with more severe CKD-aP at six months after start dialysis. These findings emphasize the need for further research on the pathophysiology and optimal treatment in dialysis patients.

Background and Aims: People with advanced stages of chronic kidney disease (CKD) undergoing hemodialysis often suffer from comorbidities that together with malnutrition and frailty contribute to a sedentary lifestyle, and cognitive and emotional impairments. Intradialytic non-immersive virtual reality exercise programs may improve the health-related quality of life and physical function of people undertaking hemodialysis. The aim of the GoodRENAI project was to test the feasibility of an intradialytic holistic virtual-reality platform designed to combine exercise with efforts to improve nutrition and psychological well-being as well as cognitive functioning and to assess the impact on physical, nutritional and psychological variables.

Method: People undergoing hemodialysis for at least 3 months who were medically stable, from Spain (Hospital de Manises), Sweden (Skane University Hospital and Karolinska Institutet), and Greece (Aristotle University of Thessaloniki) were selected and randomized into the GoodRENAI intradialysis intervention group and a control group (usual care). The GoodRENAI group
was exposed to a platform that consisted of several Virtual Scenarios (games) for each one of the targeted treatment areas: Physical Activity, Nutritional Information, Psychological Well-being and Cognitive Functionality. Specifically, these scenarios (‘games’) are aimed to make participants move (Physical Activity), learn aspects related to nutrition that they must follow (Nutritional Information), improve their psychological state (Psychological Well-being), and practice their cognitive abilities (Cognitive Functionality). The interaction with the Virtual Scenarios was designed to minimize ‘invasive’ and ‘annoying’ features by using a depth camera (AZURE Kinect), so that the patient, through the movement of their lower extremities (legs) was able to carry out the interaction. The control group carried out the usual care in the unit. The test battery included physical variables (lower-limb muscle strength, sit-to-stand to sit test 10 repetitions, 4-meters gait speed, and 6-minute walking test), nutritional variables (short-form food question, 7-point subjective global assessment, body weight, and handgrip strength), psychological variables (depression and anxiety), and cognitive variables. Differences between groups (GoodRENal vs usual care) will be analyzed with a mixed ANOVA model for repeated measures.

Results: The study so far includes 55 participants (mean age 65.4 ± 13 years), 17 females, median time on hemodialysis 48 months). The program, which starts in 2023, will last 12 weeks, until the middle of May 2023.

Conclusion: The evaluation of the GoodRENal platform will show if this is a feasible holistic treatment for improving the physical, nutritional, psychological and cognitive condition of people undertaking hemodialysis.

CANCER STATUS AND MORTALITY IN ELDERLY INCIDENT HEMODIALYSIS PATIENTS
Hyunjeong Cho1, Miran Park2, In O Sun3, Woo Yeong Park4, Jang-Hee Cho5, Soon Hye Kwon6, Won Min Hwang7, Yu Ah Hong8, Sung Joon Shin9, Sungjin Chung10 and Kyung Don Yoo10
1Chungbuk National University Hospital, Internal Medicine, Cheongju, Rep. of South Korea, 2Presbyterian Medical Center, Internal Medicine, Jeonju-si, Rep. of South Korea, 3Keimyung University Dongsan Hospital, Internal Medicine, Daegu, Rep. of South Korea, 4Kyungpook National University Hospital, Internal Medicine, Rep. of South Korea, 5Soochunhyang University Seoul Hospital, Internal Medicine, Seoul, Rep. of South Korea, 6Konyang University hospital, Internal Medicine, Daejeon, Rep. of South Korea, 7The Catholic University of Korea Daejeon St. Mary’s Hospital, Internal Medicine, Daejeon, Rep. of South Korea, 8Dongguk University Ilsan Hospital, Internal Medicine, Goyang-si, Rep. of South Korea, 9The Catholic University of Korea Yeouido St. Mary’s Hospital, Internal Medicine, Seoul, Rep. of South Korea, 10Ulsan University Hospital, Internal Medicine, Ulsan, Rep. of South Korea

Background and Aims: Chronic kidney disease and elderly people are associated with an increased risk of malignancy. But it remains unclear whether older patients with active cancer or a history of previous cancer and those without a cancer history carry the same mortality risk after initiation of hemodialysis (HD). Hence, we investigated the prognosis according to cancer status in elderly patients who started HD.

Method: Using a retrospective cohort of the Korean Society of Geriatric Nephrology, in this analysis, we included 2,085 patients older than 70 years who initiated hemodialysis between 2010 and 2017. Primary outcome of all-cause mortality was assessed using the Kaplan-Meier survival estimator and Cox proportional hazards regression analysis.

Results: At recruitment, 262 (12.6%) had a history of previous cancer and 55 (2.6%) had active cancer. During a median follow-up of 3.2 years, 1357 (65.1%) died. All-cause mortality was significantly higher in the active cancer group than in the previous cancer group and the no cancer group (85.5% vs 68.3% vs 64.0%, p < 0.002). Kaplan-Meier analysis revealed that all-cause mortality was significantly different among the 3 groups (p < 0.001, by log-rank test). After adjustment for various clinical factors, multivariate Cox regression analysis showed a strong association of active cancer with all-cause mortality (HR:1.89; 95%CI: 1.36–2.64; p < 0.001). However, previous cancer was not related to an increased risk of overall mortality (HR:1.07; 95%CI: 0.90–1.28; p = 0.448)

Conclusion: Active cancer was associated with high mortality in incident older hemodialysis patients. But patients with a history of previous cancer had a similar mortality risk compared to patients without a cancer history. Therefore, our study suggests that older cancer survivors may be able to maintain dialysis successfully.

Figure 1: Kaplan-Meier survival curve according to cancer status. All between-group comparisons were significant by pairwise log rank test.
BRAIN NATRIURETIC PEPTIDE LEVEL IN CHRONIC EGYPTIAN HEMODIALYSIS PATIENTS: ITS RELATION TO VENTRICULAR FUNCTION AND VOLUME STATUS

Alaa Sabry, Rana Elsaeed, Shaahat Ali and Zakariaf Lotfy
Mansoura, Mansoura, Egypt

Background and Aims: Volume overload is major problem in chronic hemodialysis patient and BNP level is related to volume status of the patient.

Aims: To assess BNP level in hemodialysis patient before and after HD session and to study its role as a marker for volume overload in hemodialysis patient depending on clinical findings and echocardiography parameters hemodialysis.

Method: The study was conducted on 50 patients of Nephrology and hemodialysis unit, Mansoura University Hospital. Our patients were classified according to left ventricular mass index (LVMI) into patients with left ventricular hypertrophy (LVH) (35 patients) and patients without LVH (15 patients). We classified our patients into another two groups according to predialysis BNP level to group with BNP level $>$ 100 pg/ml (33 patients) which was associated with cardiac dysfunction and group with BNP level $<$ 100 pg/ml (17 patients).

Results: In the present study, the median of pre-dialysis BNP level was 126 pg/ml and the median of post-dialysis BNP was 25 pg/ml, this demonstrate that BNP plasma level decline after the hemodialysis session.

P value $\leq$ 0.05: significant difference

There is significant difference between pre and post BP, weight and BNP pre and post dialysis in pre and post dialysis patients.

BNP pre dialysis as a predictor of LL edema, basal crepitations, congested neck veins and HTN

Among the studied patients, the mean of predialysis systolic BP in patients with high BNP level $>$ 100 pg/ml is (155.65) higher than patients with low BNP level $<$ 100 pg/ml.

The incidence of lower limb edema, congested neck veins and chest crepitations was high in the group with BNP level $>$ 100 pg/ml when compared with BNP level $<$ 100 pg/ml. In the present study, according to ROC curve, predialysis BNP level may be a marker for lower limb edema with cutoff point (140.8) pg/ml with (85%) sensitivity and (77%) specificity and shows that the best cutoff point of predialysis BNP level in prediction of neck veins is (40.4) pg/ml with (94%) sensitivity and (28%) specificity and shows that the best cutoff point of predialysis BNP level in prediction of chest crepitation is (42.8) with (82%) sensitivity and (30%) specificity.

Conclusion: In Egyptian hemodialysis patients, there is a negative correlation between BNP predialysis and weight pre and post dialysis. There is significant correlation between BNP postdialysis and systolic BP predialysis, RVD and COP. There is significant correlation between delta BNP and systolic BP predialysis and ultrafiltration volume.

CARDIAC ALTERATIONS FOUND IN PATIENTS WHO START DIALYSIS

Maria Iraola Legarra, Jose Jesus Broseta Monzo, Pedro Caravaca, Diana Rodriguez, Elena Cuadrado, Marta Farrero and Francisco Maduell
Hospital Clinic de Barcelona, Barcelona, Spain

Background and Aims: The presence of cardiac structural alterations in patients with chronic kidney disease who start renal replacement therapy is frequent. In fact, the real prevalence of heart failure is not well known due to the masking of symptoms by frequent ultrafiltration. Despite this, most deaths in these patients occur due to cardiovascular events, especially non-atheroembolic events, which are closely related to heart failure and ventricular remodeling. This study aimed to describe the echocardiographic alterations present in patients who start renal replacement therapy.

Method: Cross-sectional study to evaluate the prevalence of structural abnormalities in transthoracic echocardiography performed in patients at the time of initiating renal replacement therapy in the prevalent group of patients in kidney replacement therapy program at Hospital Clinic de Barcelona. Demographic variables and baseline drugs for heart failure were also collected.

Results: We included 170 patients of 67.84 ± 15.92 years. 115 (67.6%) were men, and 55 were women (32.4%). Of these, 124 (72.9%) were on hemodialysis, 11 (6.5%) on home hemodialysis, and 35 (20.6%) on peritoneal dialysis. Transthoracic echocardiogram findings at the beginning of dialysis showed a left ventricular ejection fraction of 47.5 ± 10.6%. It was reduced in 21 (12.4%), slightly reduced in 9 (5.3%) and preserved in 125 (73.5%) of the patients. The estimated pulmonary artery systolic pressure was 28.5 ± 3.53 mmHg. The telediastolic diameter of the left ventricle was 5.5 ± 0.71 cm, that of the interventricular septum was 1.15 ± 0.27 cm, the diameter of the left atrium was 4.5 ± 1.27 cm, its volume was 95.05 ± 56.5 mL in the biplane section and 54.3 ± 28.28 mL in the four-chamber section. There were no significant differences between groups when analyzed by type of renal replacement therapy.

Regarding valvulopathies, 47 (21.8%) had some degree of aortic stenosis, 68 (40%) had some degree of aortic insufficiency, 104 (62.2%) had some degree of tricuspid insufficiency, 118 (69.4%) some degree of mitral insufficiency. Regarding treatment, 50 (29.4%) of the patients had some RAASi, 60 (35.3%) had beta-blockers, and 2 (1.2%) had MRA.

Conclusion: The presence of structural alterations in the heart of patients initiating renal replacement therapy is practically universal and independent of the type of technique initiated. Nephrologists should become aware of these findings and seek ways to prevent and reverse these alterations as far as possible to achieve better clinical results in dialysis.

This table shows that the best cutoff point of delta BNP (predialysis BNP - postdialysis BNP) in prediction of LL edema was 17.12 pg/ml with 95% sensitivity and 71% specificity and shows that the best cutoff point of delta BNP in prediction of crepitation was 80.6 pg/ml with 97% sensitivity and 94% specificity and shows that the best cutoff point of delta BNP in prediction of HTN was 18.7 pg/ml with 97% sensitivity and 72% specificity.

#3930
EFFECT OF TWO PHOSPHATE BINDERS ON VITAMIN D LEVELS IN HEMODIALYSIS PATIENTS

Antigoni Martika, Ioanna Lampropoulou, Kalliopi Pozoukidou, Dimitrios Salvardis and Sofia Spaia
General Hospital of Thessaloniki Agios Pavlos, Nephrology Unit, Thessaloniki, Greece

Background and Aims: A recent meta-analysis highlighted the impact of different types of phosphate binders on vitamin D metabolism in patients with stage 3 CKD. Sevelamer was associated with lower serum 25(OH) vitamin D levels probably due to reduced intestinal absorption of D3 (cholecalceforol). Corresponding effects of different phosphate binders in hemodialysis patients have not been studied.

Method: We performed an observational prospective study in which 55 stable hemodialysis patients were followed for 28 months. Patients’ age was 42-91 years old and duration of hemodialysis was 2-312 months. Patients received as phosphate binders sevelamer, sucroferric oxyhydroxide or combination. The type of binders, the administration of D3 supplements, paricalcitol or etecalcetide as well as the biochemical control of the patients were recorded every two months. Serum 25(OH) vitamin D levels and the proportion of patients who required D3 supplementation to maintain 25(OH) vitamin D levels >20ng/mL were assessed.

Results: At baseline, 66% of patients used sevelamer as phosphate binder, 22% sucroferric oxyhydroxide and 18% combination, while 36% were on D3 supplements. Levels of 25(OH) vitamin D showed a significant increase after the first year of follow-up. (Dstart:16±6ng/mL vs D12months:26±10ng/mL, P = .001). After one year D3 supplementation ratio increased to 48% and remained at these levels until the end of follow-up. Taking paricalcitol or etecalcetide did not affect the results. No differences in 25(OH) vitamin D and D3 supplementation rate levels were observed between those receiving the different binders or the co administration group. No differences were observed in the biochemical markers tested as well as in dialysis adequacy.

Conclusion: In context of daily clinical practice, no differences were observed in the levels of 25(OH) vitamin D in either patients receiving sevelamer, sucroferric oxyhydroxide or combination of both as phosphate binders. Half of hemodialysis patients require cholecalciferol supplementation to maintain adequate 25(OH) vitamin D levels.
Patients were excluded if present physical or cognitive incapable to perform the proposed tests, assisted gait, uncorrected visual impairments, severe and unstable comorbidities, and hospitalization in the past three months. Postural balance was evaluated by the Mini-BESTest and posturography [a force plate recorded the center of pressure (COP) path length in a static position with eyes opened (EO) and eyes closed (EC) on a firm surface]. The normality of the data was analyzed using the Shapiro–Wilks test. The associations between Mini-BESTest score and COP path length in the EO and EC were tested using Spearman’s correlation coefficients. Then, two multiple linear regression models were constructed with COP path length in the EO and EC as the dependent variable and Mini-BESTest score and potential confounders (age, gender, diabetes mellitus, body index mass, hemodialysis efficiency index, and hemoglobin) as independent variables. A p value < 0.05 was considered as statistically significant.

**Results:** This study included 109 patients (58.4 ± 12.9 years, 57.8% male). The Mini-BESTest was correlated with COP path length in the EO (ρ = -0.365, p < 0.001) and EC (ρ = -0.279, p = 0.003). The multiple linear regression models showed an association of the Mini-BESTest with COP path length in the EO (R² = 0.28; adjusted R² = 0.23; p < 0.001) and EC (R² = 0.26; adjusted R² = 0.20; p < 0.001).

**Conclusion:** The Mini-BESTest was associated with posturography in patients on hemodialysis. Therefore, the Mini-BESTest is a feasible test to evaluate postural balance in clinical routine practice during the physical function evaluation of these patients.

---

**Abstract**

**#2905 CLINICAL OUTCOMES OF ORAL ANTICOAGULATION AND NO ANTICOAGULATION AMONG HEMODIALYSIS PATIENTS WITH ATRIAL FIBRILLATION**

Eratosthenes Polito and Grecia Darunday
Perpetual Succour Hospital, Internal Medicine, Section of Adult Nephrology, Cebu, The Philippines

**Background and Aims:** The delicate balance of risk versus benefit of oral anticoagulation in the general population is well established but the decision to use these agents in end-stage renal disease (ESRD) remains complex and difficult owing to the paucity of clinical trials and lack of substantial evidence in literature for its safe and effective use in the haemodialysis population. This study aims to determine the difference in clinical outcomes between oral anticoagulation and no anticoagulation therapy among ESRD patients on maintenance haemodialysis with atrial fibrillation.

**Method:** This is a prospective, single-center, observational study conducted in Perpetual Succour Hospital that included all ESRD patients on maintenance haemodialysis for at least 3 months with atrial fibrillation. Out of the 188 identified patients, only 69 patients were included in the study and were grouped according to how the cardiac dysrhythmia was approached either with oral anticoagulation or no use of oral anticoagulation. Basic demographic information were obtained as well as the aetiology of ESRD, CHA2DS2-VASc Score and the HAS-BLED Score. Lastly, patients were prospectively followed for a period of 12 months and were then assessed for new onset of thromboembolic events, hemorrhagic events, calciphylaxis and all-cause mortality.

**Results:** At enrolment, 59 (85.5%) patients were identified to have no oral anticoagulation therapy and 10 (14.5%) were already receiving oral anticoagulation. Ischemic strokes was more prevalent among patients who were on oral anticoagulant (80%, p < 0.0001). Patient outcomes differ significantly in terms of intracranial hemorrhage (30%, p = 0.0004) and gastrointestinal bleeding (50%, p < 0.00001) which were noted among patients on oral anticoagulation. In relation to over-all mortality, acute myocardial infarction, peripheral arterial occlusive disease and calciphylaxis, there was no significant difference between the two groups.

**Conclusion:** This study suggests that the use of oral anticoagulation did not prevent ischemic strokes in ESRD patients on maintenance haemodialysis with atrial fibrillation and its use was associated with increased risk for intracranial haemorrhage and gastrointestinal bleeding. There was no significant difference in relation to all-cause mortality, acute myocardial infarction, peripheral arterial occlusive disease and calciphylaxis between the two study groups.
Figure 1: Flow diagram illustrating the details on how the study population were obtained.

STATIN THERAPY IN CHRONIC KIDNEY DISEASE PATIENTS UNDERGOING HAEMODIALYSIS

Santa Strapcane1, Aivars Petersons1,2,3, Jānis Skride1,2, Dana Kigitoviča1,2
1Riga Stradiņš University, Faculty of Medicine, Riga, Latvia, 2Riga Stradiņš University, Internal diseases, Riga, Latvia, 3Pauls Stradiņš Clinical University Hospital, Nephrology, Riga, Latvia and 4Pauls Stradiņš Clinical University Hospital, Cardiology, Riga, Latvia

Background and Aims: In 2017, around 4 million people with end-stage renal disease worldwide were on renal replacement therapy. Haemodialysis is accounted as the most common therapy, accounting for 69% of all renal replacement therapies and 89% of all dialysis. Patients receiving haemodialysis present significantly higher risk for cardiovascular events which affect more than two-thirds of patients, making it the primary cause of morbidity (Bello et al., 2022). Statin therapy is used as primary prevention of cardiovascular risk amongst the general population; nonetheless, in patients with chronic kidney disease the benefits of statins are controversial (Fellström et al., 2009). The aim of this study is to analyze data of statins use in patients from different Latvian haemodialysis centers.

Method: A cross-sectional observational study included consecutive patients from four haemodialysis centers from June till October 2022. Patients were interviewed about disease anamnesis, comorbidities, statins and other drug usage. Data was analyzed with SPSS statistics.

Results: Among 113 included patients, 64.6% were man, mean age was 62.8±14.9 years, mean body-mass index was 26.66±5.3 kg/m². Current smokers were 14.2%. Most common primary cause for haemodialysis (47.2%) was glomerular diseases. Comorbidities as primary arterial hypertension and diabetes were diagnosed in 39.8% and 17.7% of patients, respectively. History of arterial vascular disease was present in 47 (41.6%) patients, 26 (23%) patients underwent revascularization. Anamnesis of kidney transplantation was present in 17.7%. Mean plasma concentration for total cholesterol, LDL cholesterol and triglycerides were 4.4±1.3 mmol/L, 2.5±1.1 mmol/L and 1.7±1.3 mmol/L, respectively. Mean haemodialysis period was 51.88 months ±1.7. The most common type and dosage was atorvastatin 20 mg in 21 (35%) patient, following by atorvastatin 40mg in 9 (15%) and rosuvastatin 20mg in 9 (15%) patients. Majority of statin users (49.2%) had unknown therapy starting date regarding haemodialysis, while 31.7% of patients were using statins before haemodialysis and only 19% of patients started statin therapy while undergoing haemodialysis. Patients who had transplantation were associated with 2.4 times increased usage of statins (P = .09). No significant lipid concentration difference was observed between patients who underwent transplantation and those who did not (p>0.05). LDL concentration with and without statin use was 1.97 and 2.73 (P = .03), respectively.

Conclusion: Statin therapy was related to history of cardiovascular events and revascularization, as well expressing significantly lower LDL concentration, that might be beneficial in secondary prophylaxis. History of transplantation was associated with increased statin administration.

#5622

DIALYSING THE ELDERLY: IMPACT ON THE PATIENTS’ HEALTH-RELATED QUALITY OF LIFE OUTCOME

Nur Raziana Binti Roz1, Hafizah Binti Pasi2, Wan Ahmad Syahril Rozli Bin Wan Ali1 and Che Rosie Bin Draman1
1International Islamic University Malaysia, Nephrology, Kuantan, Malaysia and 2International Islamic University Malaysia, Community Medicine, Kuantan, Malaysia

Background and Aims: The number of elderly who suffers from end stage renal disease (ESRD) is increasing and hence the dialysis therapy rate. Although dialysis increases life span, the overall benefits to elderly patients is arguably unpredictable due to the multiple comorbidities and functional impairment. Health-related quality of life (HRQOL) has been an important key outcome in the decision-making yet to date, there is no available local data of the dialysis implications on the elderly. Therefore, we aim to study on the impact of dialysis initiation on HRQOL among elderly ESRD patients.
Method: This is a prospective, multi-centered study conducted from 2021 to 2022 in 12 hospitals (aged ≥65) who started high-flux dialysis therapy. Health-related quality of life (QOL) were assessed using Kidney Disease Quality of Life-36 (KDQOL-36) questionnaire within the first month of initiation (baseline) with a follow-up review performed after six months.

Results: The study included 29 patients with the oldest was 95 years old. 27 patients underwent haemodialysis (HD) and another 2 had peritoneal dialysis. The average age of them was 62.12 and 12, respectively. 8 of them required catheterization for dialysis mobilization. All of the patients had underlying comorbidities with 25 of them had 3 and more comorbidities. Majority of the patients (n=24) were diabetic with 13 of them had an underlying ischemic heart disease. Their mean baseline haemoglobin and albumin were 8.1 g/dL (±0.3) and 34.2 mmol/L (±1.3) respectively. Only 1 of the study patients was initiated HD via a fistula which was in patients using temporary catheter. At 6 months of follow-up, 5 of the patients died due to cardiovascular events, catheter-related sepsis and one of them resorted to palliative care due to exhausted conventional vascular access. 13 patients out of 22 remained on cather for HD with 9 patients were still using temporary catheter. We observed improvement in all five domains of HRQOL assessed. The mean score of physical component summary was 33.00% (±10.58) at baseline and 41.22% (±9.54) after 6 months (P = .011). The mean scores for mental component at baseline and 6-month review were 45.53% (±14.78) and 52.95% (±10.57) respectively (P = .018). As for symptoms and problems domain, they initially scored 58.59% (±18.71) which increased to 76.61% (±16.05) after 6 months (P = .003). The scores for ‘burden of kidney disease’ and ‘effects of kidney disease’ domains were and 43.49% (±35.62) and 58.21% (±26.74) respectively at baseline with improvements to 58.85% (±31.81) (P = .026) and 76.04% (±24.65) (P = .008) after 6 months.

Conclusion: Our study showed that dialysis therapy results in significant improvement in HRQOL among elderly ESRD patients. The decision for dialysis among this group of patients is nonetheless a complex process with consideration made on individual basis followed by continuous evaluation of its effectiveness, incorporating HRQOL assessment tool in particular.

#5653
MEASURABLE IMPROVEMENT IN ABD WITH SMALL CHANGE IN HD SETTING
Nikolija Smokovska1, Nadica Misovska2, Suzana Stanojevska1, Ivica Nikolov1, Sredanka Kostadinoska1 and Marija Piperkoska1
1Diaverum North Macedonia, Skopje, Republic of North Macedonia and 2Diaverum North Macedonia, Skopje, Republic of North Macedonia

Background and Aims: Majority of the patients with chronic kidney disease on hemodialysis (CKD HD) have various bone-related pathologies covered under one clinical entity chronic kidney disease – mineral bone disorders (CKD-MBD). One of the most common is the adynamic bone disease (ABD).1 Published data are showing that changes of calcium level in HD fluid might improve the ABD.2,3 Our aim was to assess whether the lowering of the calcium level in dialysis fluid will improve the ABD in our HD patients.

Method: Prospective study was conducted in a single HD centre in a period of 12 months (01.10.2020 until 30.09.2021), with further 6 months follow up. One hundred thirty three HD patients were screened, 64 patients of them had ABD (iPTH <150 ng/ml). 53 patients were enrolled who met the inclusion criteria (age >18 years, and HD vintage >90 days) and 50 completed the study, during which the only phosphate binder used was calcium based. The calcium level content in the dialysis fluid was changed from various calcium concentration (1.5 mmol/L; 1.75 mmol/L and set to 1.25 mmol/L in the enrolled patients. Laboratory parameters were followed each month and the level of iPTH trimestally.

Results: Data from 50 patients was collected and analysed, 50.9% (n=27) males. The average age of the cohort was 69.31 years (±12.49), average HD vintage was 51.94 months (±43.82). Average HD time was 254.8 minutes (±14.71) with average blood pump 393.4 ml/min (±44.38). At study end, the iPTH level was significantly changed (p=.00001), from 67.48 ng/ml (±32.85) to 150.38 ng/ml (±92.96). 24 out of 50 patients (48%) had iPTH level >150 ng/ml, p=.0001. Calcium level changed slightly from 2.27 mmol/L (±0.15) to 2.25 mmol/L (±0.18), p=.25. The phosphate level changed from 1.29 mmol/L (±0.49) to 1.35 mmol/L (±0.48), p=.804. The alkaline phosphatase level significantly changed (p=.00002), from 82.61 IU/L (±49.5) to 118.71 IU/L (±50.23). Patients who had iPTH level >150 ng/ml at the study end had level of calcium of 2.2 mmol/L (±0.16), p=.17 compared to patients who had iPTH level <150 ng/ml (level of calcium of 2.31 mmol/L ±0.18, p=.43). There was improvement in the level of phosphate and alkaline phosphatase: 1.31 mmol/L (±0.46) vs. 1.6 mmol/L (±0.46), p=.002 and 82.57 IU/L (±57.22) vs. 130.83 IU/L (±60.24), p=.004, accordingly. Diabetes mellitus (DM) had insignificant impact on ABD in the patient cohort. 66.7% of the patients with DM (n=10) and 40% of the patients without DM (n=14) reached iPTH >150 ng/ml at study end. Intergroup comparison showed significance only in the level of calcium, DM group calcium=2.16 mmol/L (±0.1); non DM group calcium=2.29 mmol/L (±0.1), p=.01. Additionally, at study end, Karnovsky score was higher in patients with iPTH >150 ng/ml, 76.09% (±13.05); p=.009. Patients who did not reach iPTH >150 ng/ml (n=26) were further followed up for 6 months, and 10 of them reached iPTH >150 ng/ml.

Conclusion: Indirectly minor change in HD setting, as lowering the calcium level in dialysis fluid required a care of proportionate increase in phosphate binder and might improve the adynamic bone disease. Presence of diabetes did not show significant impact on ABD. However, Karnovsky score showed significant improvement, and exercise may also improve ABD in HD patients. These findings might be used as recommendation in low and middle-income countries in which pharmacological treatments for ABD are limited and/or unavailable.

#6696
COGNITIVE IMPAIRMENT IN PATIENTS ON HEMODIALYSIS EXPERIENCE FROM A CENTER IN SANTA ROSA GUATEMALA
Céselo Mazarriegos Campos1, María Palencia Pérez2, Herbert Ferrer Cuesta1, Carlos Avendaño1 and José Vicente Sánchez Polo2
1Corporación Integral de Diálisis, Guatemala, Guatemala and 2Instituto Guatemalteco de Seguridad Social, Guatemala, Guatemala

Background and Aims: Cognitive impairment in patients with chronic kidney disease (CKD) involves multiple factors such as inflammation, uremic toxins and endothelial dysfunction, having rates of up to 10.7 cases per 1000/patient year and that can increase in renal replacement therapy (RRT). The cognitive impairment can progress to dementia and this has adverse long-term outcomes such as mortality. The prevalence of cognitive impairment is 19% to 77% in patients with hemodialysis therapy. The aims of this study was determine the prevalence of cognitive impairment in hemodialysis patients and possible associated factors.

Method: A cohort study was conducted in a hemodialysis unit of Santa Rosa, Guatemala. Patients over 18 years of age were included with more than two months of having started hemodialysis and with 3 sessions per week. Patients with a previous diagnosis of dementia, with visual-hearing deficits, illiterate, a history of cerebrovascular events or psychiatric disorders and who did not agree to participate in the study were excluded. For cognitive assessment, the Montreal Cognitive Assessment tool (MoCA test) was used, taking a score of less or equal to 26 points as cognitive impairment. A value of p<0.05 was taken significant.

Results: 78 patients were screened, however 30 patients were discarded due to exclusion criteria. A total of 48 patients were analyzed. A mean age was of 51.14 years, the majority of whom were male, 40% had only a basic level of education and 38% did not know the cause of CKD. Arterial hypertension was the most frequent comorbidity and the most used antihypertensive were beta-blockers. As for medications for complications of CKD, vitamin D and erythropoietin are the most used. The patients had an average time on hemodialysis of 41.3 months, the last calculated Kt/V was of 1.73 (mean), the mean hemoglobin level was 9.9 g/dl and the mean MoCA test score performed for the study was 8.75 (±2.15).

</table>
was 23.3 points. Regarding the primary objective, it was determined that the prevalence of cognitive impairment was 67% and when analyzing the variables it was found that age and level of education are associated with greater cognitive impairment, older patients (p: 0.002) and with lower level of education (p: 0.02). In analysis the cognitive domains, it is found that those patients who present alterations in the attention and delayed recall domain are those that are statistically more associated with cognitive impairment and their counterpart those who have conserved the naming and language domain are those that are associated with having a normal global cognitive practice (Table 1). A correlation analysis was performed where it was found that there is a negative correlation which is moderate and statistically significant between age and the MoCA test score (Table 2).

Conclusion: The prevalence of cognitive impairment was 67%, age and educational level seem to be influencing factors, with older patients and those with lower single-coat level being the most affected. Within the cognitive domains, attention and delayed recall are the most affected and most associated with cognitive impairment. It is important to conduct further studies evaluating other variables that have been shown to influence cognitive status such as vitamin B12, vitamin D and homocysteine. It is important to perform cognitive evaluation of patients on hemodialysis and other RRT to have an early diagnosis and intervene early considering that cognitive impairment can progress to dementia and this is a cause of abandonment in treatment and mortality.

### 3429 HIGHER INPATIENT COSTS FOR HEMODIALYSIS PATIENTS HOSPITALIZED FOR CEREBROVASCULAR DISEASE

Aki Kuroki1 and Satoru Shimura 1

1Yokohama General Hospital, Kidney Disease Center, Yokohama, Japan

**Background and Aims:** Dialysis patients often have comorbidities that result in frequent hospitalizations. Several studies showed that inpatient costs contributed largely to the medical costs of dialysis patients. In this study, to assess the impact of comorbidities on inpatient costs in dialysis patients, we examined the association between reasons for admission and the inpatient costs using electronic medical records.

**Methods:** This was a single-center, retrospective, observational study of dialysis patients admitted to Yokohama General Hospital (300 beds) between April 2020 and March 2022. Information on patient demographics, cause of end-stage kidney disease (ESKD), dialysis duration, number of complications, and reasons for admission were collected from electronic medical records. Inpatient costs were calculated from claims data and analyzed based on patient characteristics and reasons for admission. Inpatient costs for dialysis patients were compared with those for all hospitalized patients. Data were analyzed using the Kruskal-Wallis test.

**Results:** During the observation period, 172,160 patients were admitted to the hospital, of which 169 were maintenance dialysis patients. One hundred and twenty-three of them were male, with a mean age of 73.0 years. Diabetic kidney disease was the most common cause of ESKD (n=128), followed by chronic glomerulonephritis (n=21), nephrosclerosis (n=19), and autosomal poly cystic kidney disease (n=1). The median time on dialysis was 5 years. Seventy-three patients were admitted for peripheral vascular disease, 24 for cardiovascular disease, 24 for fractures, 16 for gastrointestinal disease, 13 for cerebrovascular disease, and remainder for other conditions. Inpatient costs ranged from €764 to €7,9743, with a mean of €1,4884, and a median of €9002. Inpatient costs did not differ significantly by age, sex, time on dialysis, number of complications, or cause of ESKD. There were significant differences in inpatient costs according to the reason for admission. Patients hospitalized for cerebrovascular disease had significantly higher inpatient costs with a mean of €11,7733 and a median of €14,6623 (p = .049). During the study period, dialysis patients accounted for 0.098% of all inpatient admissions, and their medical costs were 3% of the hospital's total inpatient medical costs.

**Conclusion:** Considering the number of dialysis patients as a percentage of all inpatients during the study period, it was clear that dialysis patients had a high cost burden. Among dialysis patients, hospitalization for cerebrovascular disease was associated with significantly higher costs.

### 4654 THROMBOEMBOLIC EVENTS AND THEIR RELATIONSHIP WITH COVID-19 IN HEMODIALYSIS PATIENTS: MYTH OR TRUE?

Ignacio Cidraque1, Vicente García Román2, Alicia Sobrino Pérez3, Abraham Rincon Bello2, Kateryna Shkolenko1, Sofia Ortego1, Ana Blanco4, Diana Samaniego1 and María Eva Baró Salvador5

1 Fresenius Medical Care, Terrasa, Terrassa, Barcelona, Spain, 2 Hospital Universitario de Torrevieja, Servicio de Medicina Preventiva, Torrevieja, Alicante, Spain, 3 Fresenius Medical Care, Departamento Médico, Madrid, Spain and 4 Fresenius Medical Care, Alcobendas, Madrid, Spain

**Background and Aims:** Since the beginning of COVID-19 pandemic, there has been more than 668 million of diagnosis and more than 6 million deaths worldwide. This pandemic also has had a dramatic impact on chronic patients, such as those with end stage renal disease (ESRD) on hemodialysis (HD). Many studies have hypothesized that COVID-19 could induce a hypercoagulability state, activating coagulation cascade. Post-mortem studies revealed vascular injuries in more than 60% of lung tissues and many patients diagnosed with COVID-19 have suffered neurological pathologies, as ischemic stroke. Patients with ESRD are also at higher risk of thromboembolic events than healthy subjects.

In this study, we analyze thromboembolic events in HD patients with or without COVID-19 diagnosis.

**Method:** We performed a retrospective observational study between March 2020 and December 2022 with 4679 HD patients (2635 COVID-19 positive patients (Group 1) and 2044 COVID-19 negative (Group 2)) from 50 Spanish clinics. The baseline dates of the non COVID-19 patients were randomly selected. Follow-up time was 1 year since COVID-19 diagnosis (Group 1) or since collection (Group 2). We identified patients who has suffered any thromboembolic event during follow-up time. We compared usual clinical parameters between groups using Chi2 and Mann-Whitney U tests. Survival analysis was performed by Kaplan-Meier and Cox regression. Continuous variables were categorized to perform the Cox analysis.

**Results:** Small differences between Group 1 and 2 were found in age (70.45 (62.81-82) vs 68.94 (61-80); p < 0.001), proportion of men (63% vs 67.2%; p < 0.05), HD vintage (34 (14-71) vs 30 (11-65); p < 0.05), preHD systolic blood pressure (SBP) (140.73 (126-155) vs 142.65 (128-157); p < 0.05), plasma hemoglobin (Hb) (11.19 (10.40-11.90) vs 11.31 (10.5-12); p < 0.05) and proportion of patients with antithrombic medication (60% (22.9%) vs 401 (19.6%); p < 0.05).

No statistically significant differences were found in time to first thromboembolic event between the two groups (Figure 1). In univariate Cox regression (Table 1) thromboembolic events showed significant relationship with gender, Charlson Index above 8, preHD relative overhydration (reLOH) above 13.4% and preHD SBP above 155 mmHg. In multivariate analysis (Table 1), Charlson Index and preHD SBP showed hazard ratio above 1.5 for thromboembolic event (p < 0.05). COVID-19 diagnosis did not show strong relationship with thromboembolic events.

**Conclusion:** Publications on thromboembolic events in HD patients who have suffered from COVID-19 are scarce and with small size samples. In our large HD sample, thromboembolic events were not related to COVID-19. Only Charlson Index and preHD SBP showed a significant relationship in the multivariate analysis.
**Table 1: Cox Regression to Thromboembolic Event in 1 year follow-up.**

**IMPLEMENTATION OF CLINICAL ALARM SYSTEM IS ASSOCIATED WITH REDUCTION OF THE RISK OF INTRADIALYTIC HYPOTENSION**

Hsuanning Lin¹,², Chi Yuan Liu³, Hsiang Wei Hu⁴, Kuanyu Chen⁵, Jennie Ting Hsuan Chu⁶, Chi Hin Un⁷ and Jian-An Wang⁸

¹An Nan Hospital, China Medical University, Tainan, Taiwan, Nephrology Division, Tainan City, Taiwan, Rep. of China, ²National Cheng-Kung University, Institute of Information Management, Tainan City, Taiwan, Rep. of China, ³Department of medicine, Taipei Medical University, Taipei, Taiwan, Taipei City, Taiwan, Rep. of China, ⁴Department of Artificial Intelligence in Healthcare, International Academy of Biomedical Innovation Technology, United States of America, ⁵Acusense Biomedical Technology Corp, Tainan, Taiwan, Tainan City, Taiwan, Rep. of China and ⁶University of California Riverside, Masters of Engineering specialization in data science, North Vancouver, Canada

**Background and Aims:** Intradialytic hypotension (IDH) plays an essential role in hemodialysis. IDH prevalence can be up to 8% to 40% [1], according to research. Furthermore, research shows that IDH positively correlates with severe complications such as non-occlusive mesenteric ischemia[2], critical limb ischemia[3] and tissue ischemia, which leads to irreversible damage, even increasing the chance of infection. Many causes and risk factors result in IDH, such as excessive weight gain during dialysis, cardiovascular dysfunction, and improper use of blood pressure-lowering drugs[1]. Therefore, it still relies
on experienced medical professionals to monitor patients' blood pressure to beware of the risk of developing IDH. However, this increases the workload on medical professionals and does not provide standard or more objective early warning indicators of hypotension for new medical professionals.

**Method:** Selection of experimental and control group: In this study, we included 81 subjects that received hemodialysis in Tainan City Municipal Annan Hospital from January 2021 to August 2022. The control group was retrospective data collected from January 2021 to August 2021. Then, from January 2022 to August 2022, we implemented our IDH predicting system and took subjects' data from this interval as the experimental group to compare the incidence of IDH with the control group.

**IDH prediction system monitoring interface:** After integrating with the hemodialysis dataset, our prediction system will predict patients' systolic pressure and the likelihood of IDH in the next 30 minutes. As soon as the system detects that the patient will encounter hypotension, it sends warning signals, blood pressure and IDH incidence probability predictions to the monitoring interface to alert medical professionals. Furthermore, our system also supports multi-bed monitoring, which can significantly increase the efficiency of monitoring during hemodialysis.

**Results:** After implementing the IDH prediction system, the outcome yielded an IDH incidence of 6.12% in August 2022. Compared to the control group, when the IDH system was not yet implemented, which yielded an IDH incidence of 9.34%, it showed a reduction of 34.5% in IDH cases. Furthermore, the average reduction in IDH rate each month was 12%.

**Conclusion:** The present study demonstrated that implementing the IDH predicting model may efficiently reduce the incidence of IDH. However, along with the IDH warning multi-bed monitoring interface, medical professionals must develop a standard procedure to deploy when noticing the warning signals. As a result, this may further reduce the incidence of IDH during hemodialysis sessions.

**ANALYSIS OF RISK FACTORS FOR CUTANEOUS CALCIPHYLAXIS IN HEMODIALYSIS PATIENTS**

Zhimin Ren¹, JJ Zhou²,³ and Ting Xiang³

¹The Third People's Hospital of Sichuan Province, Kidney Research Institute, Division of Nephrology, chengdu, P.R. China and ²West China Hospital, Sichuan University, Kidney Research Institute, Division of Nephrology, chengdu, P.R. China

**Background and Aims:** Risk factors with cutaneous calciphylaxis were analyzed in hemodialysis patients.

**Method:** Clinical data of hemodialysis patients who were diagnosed with cutaneous calciphylaxis and admitted to Sichuan University West China Hospital and hospitals in West China Nephrology Union were retrospectively collected. Noncalciphylaxis patients in hemodialysis center of West China Hospital Sichuan University were randomly selected as the controls. Group 1: The 1:1 matched cases and controls by age (year, within ±3) and duration of hemodialysis (month, within ±20%) as matching factors. Group 2: The controls were matched to cases in a 1:1 ratio by gender and duration of hemodialysis (month, within ±20%) as matching factors. Univariate and multivariate binary Logistic were used regression analysis model, screening for statistically significant variable factors.

**Results:** Most of cutaneous calciphylaxis patients were male and elderly. Group 1: The univariate regression analysis showed that gender, diabetes mellitus, coronary heart disease are significantly associated with calciphylaxis. Laboratory examination results showed that parathyriod hormone (PTH), serum albumin, serum phosphate, C reactive protein (CRP) were significantly with calciphylaxis. Diabetes mellitus, lower albumin, higher serum phosphate and higher CRP were independent risk factors after multivariate analysis. Group 2: The univariate logistic regression analysis showed that age, BMI, coronary heart disease, diabetes were significantly associated with calciphylaxis. Laboratory examination showed that alkaline phosphatase (ALP), PTH, serum albumin and CRP were all significantly associated with calciphylaxis. Diabetes mellitus, lower albumin, higher PTH, and higher CRP were independent risk factors after binary Logistic analysis.

**Conclusion:** Diabetes mellitus and higher CRP, higher PTH, higher serum phosphate, lower albumin, are important high risk factors.

**ORAL HEALTH STATUS IN DIABETIC AND NON-DIABETIC PATIENTS ON MAINTENANCE HEMODIALYSIS TREATMENT**

Emilija Rambabova¹, Irena Rambabova-Bushljetik¹, Lada Trajcheska², Zhaklina Shterjova-Markovska², Vasiliki Krecova¹, Gordana Gjorgjievska³, Mirjana Popovska-Spasovska³ and Mile Carcev³

¹University Goce Delcev, Stip, Republic of North Macedonia, ²University Clinic of Nephrology, Skopje, Republic of North Macedonia, ³Nefro Plus, Skopje, Republic of North Macedonia and ⁴University Clinic for Dentistry, Skopje, Republic of North Macedonia

**Background and Aims:** Uremic toxins and inflammation influence the oral health in patients on maintenance hemodialysis treatment. The presence of diabetes additionally aggravates the oral status. Aims: To compare the oral health status in diabetic and non-diabetic patients on different dialysis modality treatment.

**Method:** Observational, cross-section, monocentric study was conducted in 72 hemodialysis (HD) patients divided into two groups regarding the presence of Diabetes mellitus (DM). Patients were routinely designed to hemodialysis or hemodiafiltration (HDF) during the previous year of HD treatment. Demographic characteristics as patients age, dialysis vintage, laboratory inflammatory markers as C-reactive protein (CRP), albumin and Interleukin 6 (IL-6) were measured at the start of the study. Also, uremic small and middle molecules as blood urea nitrogen (BUN), creatinine, β2-microglobulin (β2M), myoglobin, albumin, free light chains kapp (FLC-k), and free light chains lambda (FLC-λ) were analyzed. Patients were examined by a dentist specialist scoring the oral hygiene index (OHI) by Greene Vermillion as good, fair and poor. Presence of tooth fillings and extractions, caries, hyperkeratosis, periodontal disease, erosions, ulceration, erythema, pigmementsations, saburral tonque and uremic fetor were notified. Gingival hyperplasia (GH) was scored (1-3) with 3 for worst score and the tooth color was scored 1-3, signing 1-
Results: The patients from group 1 - with DM (N=26) didn’t differ from the non-diabetic group (N=46) in respect of gender, age and dialysis modality but had significantly shorter dialysis vintage (48.68 ± 37.45 vs. 88.13 ± 63.29, \( P = .02 \), respectively). From the inflammatory markers only IL-6 was significantly higher in diabetics (\( P = .03 \)). All the analyzed uremic toxins – small and middle molecules also didn’t differ between the two groups. Diabetic patients were at 3 fold risk for manifestation of fissure, 4 fold risk for pigmentation and 7 fold risk for erythema (OR 3.58; CI:1.017-12.380, \( p = 0.003 \); OR 4.12; CI:0.684-22.870; \( p = 0.02 \), OR 4.84; CI:1.343-17.498, \( p = 0.000 \); OR 7.25; CI:1.123-46.880, \( p = 0.000 \), respectively). GIH was more likely to be present in diabetic patients (35%, 54%, 11% vs 83%, 15, 0%, \( p = 0.000 \), respectively). The presence of hyperkeratosis, periodontal disease erosions, caries, extractions, tooth fillings and the tooth colour didn’t differ between the groups. Diabetics were found with higher percentage of bad oral hygiene index (38% vs 20%), but the overall comparison of OHI showed no significant difference.

Conclusion: Oral health is significantly deteriorated in dialysis patients, especially in those with inflammation. Diabetic patients are at higher risk of developing changes in the oral health status.

Results: Among 70 patients maintained on regular hemodialysis, 42 patients have normal hemoglobin level (above 12 mg/dl with high serum ferritin > 300 ng/ml). They classified into two group: A 26 patients with high ferritin, high TSAT >20%, and normochromic red blood cells, A 16 patients with high ferritin level, low TSAT <20% and hypochromic red blood cells. Among the 26 patients, 17 male and 9 female, and among the 16 patients, 11 male and 5 female. The 26 patients have mean age of (41 +/- 13) and the 16 patients have mean age of (39 +/- 10). No significant difference between the two groups regarding sex and age with p value (0.5 and 0.1 respectively). Assessment of cognitive function by SLUM score revealed regarding normal group (4 have normal score, 18 have mild impairment of cognitive function and 4 have dementia score) and the iron deficient group (4 have normal score, 9 have mild impairment of cognitive function and 3 have dementia score) with no statistically different between the two group (\( P = .6 \)).Regarding quality of life, no statistically difference was found between the two groups regarding physical functioning (\( p = 0.18 \)), role physical (\( p = .11 \)), bodily pain (\( p = 0.33 \)), general health (\( p = 0.5 \)), vitality (\( p = .41 \)), social functioning (\( p = .2 \)), role emotional (\( p = .4 \)), and mental health (\( p = .21 \)).

Conclusion: Non-anemic hemodialysis Patients with Functional iron deficiency has no statistically different regarding neurocognitive function and quality of life from normal iron non-anemic patients.

### #6917

**IMPACT OF FUNCTIONAL IRON DEFICIENCY IN NON-ANEMIC HEMODIALYSIS PATIENT ON NEUROCOGNITIVE AND QUALITY OF LIFE: A SINGLE CENTER CROSS-SECTION STUDY**

Ahmed Mohamed Naguib Attiya1, Hoda Abdulaziz2, Salwa Elwasi3, Donia Gad1, Walaa Saad1, Hager Abd el Aziz1, Samir Sally1 and Mohamed Sobh1

1Urology & Nephrology Center Mansoura University, Egypt and 2Mansoura University Hospitals, Egypt

**Background and Aims:** The clinical paradox of high ferritin levels and low TSAT is a condition known as ‘functional iron deficiency.’ This occurs when the body has adequate iron stores, as indicated by high ferritin levels, but the iron is not available for use in the body, as indicated by low TSAT levels. This can be caused by inflammation, chronic disease, or other conditions that interfere with the body’s ability to absorb and utilize iron. Hemodialysis patients may suffer from both absolute and functional iron deficiency. Most studies were directed to study effect of absolute iron deficiency even patients may suffer from both absolute and functional iron deficiency. This paradox is encountered more often in those with inflammation. Diabetic patients are at higher risk of developing changes in the oral health status.

**Conclusion:** Oral health is significantly deteriorated in dialysis patients, especially in those with inflammation. Diabetic patients are at higher risk of developing changes in the oral health status.

### #2736

**THE PHASE ANGLE AS A PREDICTOR OF SARCOPENIA IN NORMOHYDRATED PATIENTS ON HEMODIALYSIS: A MULTICENTER STUDY**

Yanet Parodis López1, Sebastian Hillebrand Ortega1, Francisco Alonso Alman1, Nicanor Vega1 and Gloria Anton-Perez2

1Centro de Hemodialisis Avericum, Las Palmas de GC, Las Palmas de GC, Spain and 2Avericum Hemodialysis Center, Las Palmas de GC, Las Palmas de GC, Spain

**Background and Aims:** The skeletal muscle index (SMI) is an impedance parameter that assesses muscle mass, and the phase angle (PA) is inversely related to strength and muscle mass in hemodialysis patients. Both parameters may represent useful and inexpensive tools to identify sarcopenic patients. The phase angle (PA) are evaluated as markers of muscle mass and strength, respectively.

**Method:** The presence of sarcopenia was analyzed in 348 normohydrated patients in 5 hemodialysis centers by means of vector bioimpedance using the BIA101 BIVA PRO equipment. To do this, the skeletal muscle index (SMI) and the phase angle (PA) are evaluated as markers of muscle mass and strength, respectively.

**Results:** Mean SMI and PA were 8.64 ± 1.5 and 5.2 ± 0.9. The mean PA was 5.6 ± 0.9 in those with SMI within normality (9.2 ± 1.9). In moderate and severe sarcopenics patients, the means of SMI (8.9 ± 1.2 vs 7.5 ± 0.9) and PA (5.3 ± 0.86 vs 4.7 ± 0.67) were significantly lower (\( p < 0.001 \)) (Table 1). In patients on standard hemodialysis, the PA (\( P = .02 \)) and the SMI (\( P = .004 \)) were significantly lower. The PA (\( P = .014 \)) and the SMI (\( p < 0.01 \)) were significantly lower in the female gender but the number of sarcopenic patients was higher among the men (\( p < 0.001 \)). The cut-off value of PA, which predicted a higher risk of sarcopenia, was 3.5 in all patients (95% CI, 0.60-0.71; \( P = .0001 \); 100% sensitivity, 96% specificity); 3.55 for men (95% CI, 0.57-0.78; \( P = .003 \); 100% sensitivity, 94% specificity) and 3.65 for women (95% CI, 0.60-0.73 ; \( P = .0001 \); 100% sensitivity, 96% specificity) (Fig. 1).

In the logistic regression analysis, male gender, standard hemodialysis technique, and PA were associated with a higher risk of sarcopenia (Table 2).

**Conclusion:** PA is a good predictor of sarcopenia in hemodialysis patients.

**PREVALENCE OF AMPUTATION IN HD PATIENTS: A DIALYSIS PROGRAM WITHOUT SOCKS**

Rosa Sánchez Hernández1, Rocío Zamora González-Mariño1, Laura Rodríguez-Osorio Jiménez2 and Beatriz Durá Gúrpide3

1Spain

**Background and Aims:** Peripheral arterial disease affects very commonly CKD patients on dialysis. Frequently such injuries precede severe complications that lead to hospitalizations, amputations and even death.

**Objectives:** Study the prevalence of ulcers and amputation on dialysis, analyze related risk factors, post-surgical results and establish a prevention program.

**Method:** Descriptive, observational, retrospective (7 years), single-center study in patients with CKD on dialysis.

**Results:** 202 patients (12 PD 190 HD), 67 active and 135 off dialysis, 127 men 75 women. Average age 69 years. Average time on dialysis 47 months. Vascular access: 56%, native fistula 37%, catheter 7%, prosthesis. Cause CKD 30.2% ND, 22.8% NAS. 95.54% HBP, 46.53% DM 26.73% Ischemic heart disease, 31.19% chronic ischemia, 26.24% had intermittent claudication, 12.38% had all the comorbidities indicated. Higher comorbidity in males M:F 4:1. 53.47% ex-smokers or active habit.

Ulcers 29.7% (40 men 20 women), 76.67%, diabetics. Half of the patients with DM (48.94%) presented ulcers. The most frequent was vascular ulcer (43.67%) followed by that associated with diabetic foot (26.67%) and pressure ulcer 15%. Amputations (11 major and 13 minor) in 24 patients (16 men 8 women) with a prevalence: overall 12%, DM 22.34%, with ulcers 40% and 46% if they are diabetics. Analytics in amputees. Average: PTH 352 ng/dl, Phosphorus 4.4 mg/dl, Vitamin D 19 mg/dl, Albumin 3.3g/dl, hypercholesterolemia in 20%. 17 patients with chronic ischemia were revascularized (76.47% ended in amputation).

Mortality: 88 patients died (43.56%), of which 41 were patients with ulcers (68.33%) and 20 were amputees (83.33%, 3 early mortality and 17 late mortality).

**Conclusion:** The prevalence of amputations on dialysis is high. Most are male, DM with high cardiovascular comorbidity and a previous history of ulcers. Mortality increases in patients with CKD and ulcers and amputees. There is a need for 11 dialysis without socks® programs for early detection of dialysis ulcers to reduce the incidence of amputees.

### #4310

**DEVELOPMENT OF A HOME DIALYSIS PATIENT SUPPORT SYSTEM WITH EXERCISE FUNCTION PART 1 - SYSTEM DEVELOPMENT AND EVALUATION**

Tokuo Umeda1,2, Akiko Okawa4, Natsumi Yamamoto5 and Yuki Sekine6

1Machida, Japan, 2Kitasato University, Machida, Japan, 3MIE Prefectural College of Nursing, Tsu, Japan, 4MIE Prefectural College of Nursing, Tsu, Japan, 5MIE Prefectural College of Nursing, Tsu, Japan

**Background and Aims:** Although many people use communications infrastructure, direct connection of electronic medical records to the Internet is restricted at medical institutions in Japan. Therefore, patient information outside the medical institution cannot be viewed on systems inside the medical institution. We are developing a safe and secure dialysis support system that connects dialysis patients and medical institutions, which is separate from the system within medical institutions. We have developed a dialysis support system that can share vital data, dialysis records, meal records, etc., between patients and medical institutions.

In this study, to support dialysis patients’ exercise and its continuation, we created an ergo-storage device combining an ergometer and storage device for this research and added functions to the existing dialysis support system. This system with additional exercise function could encourage patients to exercise, store the amount of exercise as the amount of electricity used, this electricity represented a reward to the patient for exercising. These additional features allow the patient to exercise at home on both dialysis and non-dialysis days.
Method: An ergometer was used as exercise equipment for dialysis patients with a hub dynamo to convert the rotations of the ergometer through a belt into electricity. This allowed the dynamo to take over the rotation of the ergometer. In addition, we developed a new circuit that converts the power generated by the dynamo to USB voltage. A simple USB voltage and current checker was added to allow the integrated power to be displayed making it possible to visualize momentum as power generation. In addition, the generated power could be stored in the USB charger. To record the amount of exercise of the patient, the information from the ergometer was output to a tablet in CSV format. This CSV file was sent to the developed system and linked with the patient information in the existing system. This system made it possible to visualize and display the exercise information along with the patient’s daily dialysis information and meal information on the developed system.

Results: Momentum could be converted to electrical energy using the ergo-storage device. The patient could now see and store the amount of exercise they have done, enabling the patient to exercise on both dialysis and non-dialysis days. As the amount of exercise could be visualized at a glance, the patient was encouraged and prompted to exercise daily. In addition, as the amount of exercise could be stored as electricity, this electricity represented a reward to the patient for exercising. The patients reported that it was good to be able to exercise instead of having a quota, and that they were able to continue exercising. Patients began exercising voluntarily instead of being forced to exercise by health care workers. In addition, it was possible to link the system with the patient’s dialysis records and share the amount of exercise, making it easier for medical professionals to understand the patient’s physical condition.

Conclusion: A function that allows dialysis patients to exercise was added to the developed system. Using this system, patients and medical institutions could share dialysis records, such as the patient’s amount of exercise. The patients could exercise on both dialysis and non-dialysis days, and the amount of exercise and dialysis records could be shared with medical institutions. In addition, the amount of exercise was stored as electricity, which increased the patient’s motivation to exercise. The patients began to exercise voluntarily. This research was supported in part by Gakushin Kaken (JP20H03982).

ULTRASOUND EXAMINATION OF THE SUBCUTANEOUS PERITONEAL CATHETER TUNNEL IN CASES NOT RELATED TO INFECTION
Matthias Zeiler1, Gilda Fioravanti1, Giuseppe Fioravanti1 and Antonio Granata2
1Ospedale "C. e G. Mazzoni", Nephrology and Dialysis Unit, Ascoli Piceno, Italy and 2Ospedale "Cannizzaro", Nephrology and Dialysis Unit, Catania, Italy

Background and Aims: According to the guidelines of the International Society of Peritoneal Dialysis possible indications of ultrasound (US) examination of the catheter tunnel are suspected tunnel infection, initial evaluation of exit-site infection without clinical signs of tunnel involvement, follow-up of exit-site and tunnel infection after treatment and relapsing peritonitis episodes. Other authors suggest US examination of the subcutaneous tunnel in every case of peritonitis. We analyzed the associations between US findings at the catheter
### Table 1: Association between ultrasound findings and their clinical impact.

<table>
<thead>
<tr>
<th>Ultrasound findings</th>
<th>Clinical impact</th>
</tr>
</thead>
<tbody>
<tr>
<td>Distance of the external cuff from exit site</td>
<td>Risk of cuff infection or cuff extrusion</td>

<tr>
<td>Direction of the catheter</td>
<td>Risk of catheter dislocation/malfunction</td>
</tr>
<tr>
<td>Position of the inner cuff</td>
<td>Risk of adhesion/malfunction in the case of intraabdominal position</td>
</tr>
</tbody>
</table>

### Method:
The subcutaneous tunnel of the peritoneal catheter was examined with a linear probe of 6.5-10 MHz having covered the exit site with a transparent adhesive film-dressing. For the retrospective investigation covering the last 10 years, we selected peritoneal dialysis patients who performed an US examination without clinical signs or suspect of exit site or tunnel infection. During the US examination, the distance of the external cuff from the exit site, the presence and extend of leakage or size of a hematoma (along the catheter and at the surgical site), the proximity of the inferior epigastric artery to the catheter, the configuration of the subcutaneous tunnel (including inclination and direction of the catheter at the entrance into the peritoneal cavity) and the position of the inner catheter cuff were documented.

### Results:
Several US findings were found to be associated with a specific risk or need of intervention in the follow up of the patient. The following table reassumes the US findings and the respective clinical impact.

### Conclusion:
US findings documented during the examination of the catheter tunnel in cases related to infection have a certain clinical impact due to their association to a specific risk or need of intervention, and therefore should not be overseen during the examination.

1Hospital de Santa Cruz, Nephrology, Carnaxide, Lisboa, Portugal, 2Centro Hospitalar Universitário do Algarve - Hospital de Faro, Nephrology, Faro, Portugal, 3Hospital dr. Nélio Mendonça, Nephrology, Funchal, Madeira, Portugal, 4Hospital de Santa Cruz, Cardiology, Carnaxide, Lisboa, Portugal, 5Hospital de Santa Cruz, Nephrology, Carnaxide, Lisboa, Portugal and 6Hospital de Santa Cruz, Carnaxide, Lisboa, Portugal

Pimenta, G. Afonso, R: both authors contributed equally

### Background and Aims:
Anxiety between the two groups considered prior to psychological support was significantly higher in patients on peritoneal dialysis than in patients on hemodialysis (P = .31). The decrease of State Anxiety was bigger in patients on peritoneal dialysis (P = .50) than in patients on hemodialysis (P = .38). There was no significant difference between patients supported by in-person or on-line therapy. Further randomized studies are warranted to confirm safety and clarify the benefit of this therapy in PD patients with HFrEF.

### Conclusion:
Our results suggest that ARNI can be used safely in patients under PD with major cardiovascular risk. Further randomized studies are warranted to confirm safety and clarify the benefit of this therapy in PD patients with HFrEF.

### #4650

**EVALUATION OF PSYCHOLOGICAL SUPPORT IN HEMODIALYSIS AND PERITONEAL DIALYSIS PATIENTS**

Davide Marturano 1,2, Sabrina Milan Manani 1, Grazia Maria Virizi 1, Chiara Gechelin 1, Ilaria Tantillo 1, Claudio Ronco 1 and Monica Zanella 1

1San Bortolo Hospital and IRIRR, Nephrology, Vicenza, Italy and 2Department of Medicine, Nephrology, Dialysis and Transplantation Unit, University of Padua, Italy

### Background and Aims:
Chronic kidney disease is one of the chronic diseases with the biggest social impact. The quality of life of the patients with chronic kidney disease stage V is strongly affected by the recommended therapies. The choice between hemodialysis, peritoneal dialysis, transplantation or conservative management of chronic kidney disease is shared between clinician and patient. Caring of chronic kidney disease and especially renal function replacement treatment involves a commitment to the patient and family tissue that have an important influence on patient anxiety. Such situation alters the State-Anxiety, that expresses a perception connected to a specific context and it overlaps with Trait Anxiety; that evaluates relatively stable aspects of being prone to anxiety. Anxiety can be split into two components, State Anxiety, expressing a context-related feeling, and Trait Anxiety, expressing an intrinsic personality condition.

The aim of this study was to investigate the presence of anxiety in patients on hemodialysis and peritoneal dialysis and the benefit that psychological support (either in-person or on line) could produce in these populations.

### Method:
The study group enrolled 24 patients: 13 were under haemodialysis and 11 were peritoneal dialysis patients. All patients were older than 18 years old and were followed at the Nephrology Hospital San Bortolo in Vicenza. Patients underwent eight sessions of psychological support. The first and the eighth sessions have been held in-person, while the others either in-person or on-line according to the patients’ preference. Nephrologists select patients to be treated according to their needs of psychological support. The State-Trait Anxiety Inventory (STAI), which evaluates Trait and State Anxiety, was submitted during the first and eighth sessions. Statistical analysis was performed by software SPSS.

### Results:
The two groups were homogeneous for age, sex and comorbidities. There was no significant difference in the components of Trait and State Anxiety between the two groups considered prior to psychological support therapy (P = .38 and P = .64, respectively). Trait and State Anxiety decreased significantly after treatment both in hemodialysis and peritoneal dialysis (both p < 0.001). Trait Anxiety had a greater decrease compared to State Anxiety in both groups. The decrease of Trait Anxiety was similar in the two groups (P = .31)(Fig. 1). The decrease of State Anxiety was bigger in patients on peritoneal dialysis compared to hemodialysis patients: these patients had a greater benefit from the psychological support (P = .05)(Fig. 1). Furthermore, there was no significant difference between patients supported by in-person or on-line treatments (P = .68).

### Conclusion:
Psychological support in patients with renal replacement treatment leads to a reduction in Trait Anxiety and State Anxiety, regardless if the replacement therapy is hemodialysis or peritoneal dialysis. This allows patients to better tolerate the burden that the disease entails and to improve compliance to treatment. Psychological support could also help physicians in order to obtain better results with a stronger therapeutic alliance.
**Figure 1:** Comparison in terms of Trait and State-Anxiety in Peritoneal dialysis (PD) and Hemodialysis (HD) patients. We analysed the difference (delta) in STAI results for Trait and State Anxiety between the first and at the and eighth sessions.

**#5941**

**SERUM LEPTIN AND MALNUTRITION IN PERITONEAL DIALYSIS PATIENTS: A CONNECTION YET TO BE FOUND**

Ana Trigo, Ana Rita Ramos, Rui Duarte, Ana Rita Valerio Alves, Hernâni Gonçalves and Paulo Santos  
Torres Novas, Nephrology, Torres Novas, Portugal

**Background and Aims:** Leptin is a hormone responsible for the modulation of the satiety signals and that it is known for being increased in patients undergoing Peritoneal Dialysis (PD) treatment. Nevertheless, conclusions about its role in the malnutrition associated with this technique remains to be done. Our study aimed to characterize the nutritional state of a Portuguese program of PD and to establish the impact that leptin levels had on it.

**Method:** A cross-sectional study was performed involving 28 patients of a PD program. To characterize the patients nutritional status we collected the following data: anthropometric measurements (weight, body mass index (BMI), fat tissue index and lean tissue index using Fresenius® Body Composition Monitor), analytical values (albumin, total proteins, total cholesterol, high-density lipoprotein cholesterol, low-density cholesterol, triglycerides, leptin serum levels), protein metabolism (normalized protein catabolic rate (nPCR), normalized diastylate protein loss (nEPL), normalized urine protein loss (nUPL), normalized total protein loss (nTPL) and normalized dietary protein requirement (nDPR)) and peritoneal dialysis adequacy (total, renal and peritoneal kT/v; total, renal and peritoneal creatinine clearance). The collected data were statistically analyzed and correlations were made using Mann-Whitney U test and Spearman test, depending on the variable type.

**Results:** 7 (25%) patients were females, and the mean age was 59.5 years old (± 14.31). The mean dialysis vintage was 27.04 months (± 20.14) and the majority (n=23, 82.1%) preformed automated peritoneal dialysis (APD). Regarding the nutritional status, the mean BMI, FTI and LTI was 26.64 kg/m2 (±4.39), 14.24 kg/m2 (±5.47) and 11.62 kg/m2 (±2.52) respectively. 57.1% (n=16) had serum albumin below 3.5 mg/dL, with a mean phosphorus of 5.01 mg/dL (±0.72) and a mean leptin of 28.88ng/ml (±28.44). The serum leptin was 5.4 times higher than the adjusted value for BMI in the population without kidney disease. The adjusted serum leptin for BMI was different between sex (U=15, P = .001) and it was positively correlated with total (ρ=0.47, P = .012) and high-density lipoprotein (HDL) cholesterol (ρ=0.535, P = .003). It was not associated with the protein metabolism (nPCR, nEPL, nUPL, nTOL and nDPR), albumin or total proteins and PD adequacy.

**Conclusion:** Leptin values independent of BMI are significantly higher amongst patients on PD. Alike the healthy population, women on PD are also prone to have higher serum leptin values. Although studies are still controversial about the association between this hormone and cholesterol, in this population there is a positive correlation. As so, hyperleptinaemia cannot yet be associated with the malnutrition that is generally present amongst PD patients, but it must be considered as a contribute to the already known increased cardiovascular risk.

**#5992**

**PERITONEAL DIALYSIS-RELATED PERITONITIS: A SINGLE CENTER EXPERIENCE**

Ana Bulatović1,2, Jelena Bjeđov1,2, Tatjana Damjanović1,2, Aleksandar Janković1,2, Verica Todorov Sakic1, Petar Djuric1,2, Nada Dimkovic1, Radonimir Naumovic1,2  
1Zvezdara University Medical Center, Clinical Department for Nephrology and Dialysis, Belgrade, Serbia, 2University School of Medicine, Belgrade, Serbia and 3Medical Academy, Serbian Medical Association, Belgrade, Serbia

**Background and Aims:** Peritonitis is a common and severe complication in Continuous ambulatory peritoneal dialysis (CAPD). A high peritonitis rate affects PD patients' technique survival and mortality. The aim of this retrospective study is to assess epidemiological aspects, microbiology presentation with antibiotic resistance and clinical outcomes for patients with acute CAPD peritonitis during 5-year period.

**Method:** The study included all patients treated by CAPD between the 1st of January 2017 and 1st of January 2022 in the Clinical Hospital Center Zvezdara. We included prevalent patients on CAPD, and analyzed demographic, clinical and microbiological data, and patient’s outcomes during 5 year period. The data was collected from patient records, medical history and processed in SPSS.

**Results:** This study included 119 patients treated by PD of which 24 (8.13%) had one or more acute episodes of CAPD peritonitis in the designated period. The mean age of the population was 69±9 years, 54% were male, 20% had diabetes mellitus and 60% arterial hypertension as cause of end stage renal disease. During follow up it was diagnosed 41 episodes of CAPD peritonitis. The main characteristics of patients with peritonitis were turbid liquid (100%), abdominal pain (73%) and fever (43%). Gram staining revealed that 53% were gram-positive, and 10% were gram-negative. The most frequent bacterial specimen was Staphylococcus epidermidis (11) followed by Streptococcus viridans (6), sterile culture (9), Staphylococcus aureus (3) and other organisms less than 2 episodes. The peritonitis rate was 1 episode per 27.36 patient-months, or 0.44 episodes per patient year. Resistance to Ampicillin and Penicillin occurred most often. In 2 patients, PD peritonitis was present once each, with multi-resistant bacteria: Klebsiella pneumoniae which was treated with parental administration of Tigacycline and Methicillin-resistant Staphylococcus aureus (MRSA) which was treated with parenteral administration of Moixifloxacin and Clindamycin. Out of 24 patients, 2 (8.33%) had 4 episodes of peritonitis, 3 (12.5%) had 3 episodes of peritonitis, 25% had 2 episodes of peritonitis, and the rest (54.16%) were had only one each. Only one patient had an episode of relapsing peritonitis. During 5-year period, 1 (4%) patient died of acute CAPD peritonitis caused by Proteus mirabilis, 7 (29%) died of other causes, 11 (46%) were transferred to hemodialysis and 5 (21%) are still receiving treatment by CAPD modality. CAPD peritonitis was the reason for technical failure in 20 patients.

**Conclusion:** PD-associated peritonitis is serious infective complication which could influence the outcome of PD patients, including technique survival. The rate and outcomes of peritonitis in our patients were slightly above of current recommendations.
ANEMIA IN PERITONEAL DIALYSIS
Andrea Alelo Oltra, Diana Manzano, Adoración Martínez, Ines Llamas Sarria, Jose Luis Albero Dolon, Pedro Pablo Ortuño, Manuel Lanuza, Julian Navarro Martinez, Pablo Navarro Martínez and Juan Cabezuelo-Romero
Spain

Background and Aims: Anemia is one of the most frequent complications of chronic kidney disease (CKD), affects quality of life and increases morbidity and mortality. Prevalence of anemia in patients on peritoneal dialysis (PD) is 83% according to the RIKAS study. Diagnosis of anemia in CKD is set at a hemoglobin (Hb) below 13 g/dL in men and less than 12 g/dL in women. These values serve to define the diagnosis, but not to indicate treatment. Treatment is based on the use of erythropoiesis stimulating agents (ESA) and iron therapy. Absolute iron deficiency (ferritin less than 100 ng/ml and transferrin saturation index (TSAT) less than 20%) and functional iron deficiency (TSAT less than 20% with normal ferritin), require correction with oral or intravenous iron before the use of ESA. Treatment with ESA is indicated when Hb is below 20% with normal ferritin), require correction with oral or intravenous iron.

Results: N = 58 patients, 64% men and 36% women. The mean age was 61.3 +/- 15.54 years. 31% of patients were CKD secondary to glomerulonephritis (predominant etiology). 5% had no cardiovascular risk factors (CVRF), 48% between one and two and 47% more than three. 74% on continuous ambulatory peritoneal dialysis (CAPD). Mean time of dialysis 28.74 +/- 25.05 months. Mean residual diuresis in 24 hours 1199.22 +/- 703.14 cc.

Prevalence of anemia 74%. Mean Hb of 10.97 +/- 1.29 g/dL with 78% of patients with values between 10-12 g/dL. Mean ferritin of 356.79 +/- 226.84 mg/dL with 79% of patients between 100-500 mg/dL. 83% received treatment with ESA, 33% with intravenous iron. No patient received oral iron. 4 patients needed of blood transfusion and 3 of them due to bleeding (2 gastrointestinal bleeding and 1 urinary bleeding).

Conclusion: Despite having more patients on CAPD, the number of peritonitis episodes per patient-year were in a decreasing trend. This was the result of the implementation of empirical first line intra-peritoneal antibiotics as part of the CAPD Peritonitis Management Protocol in 2015 and Decontamination Protocol in 2016.

We observed a statistically significant association between higher residual diuresis volume and adequate anemia control (P = .042) and between lower creatinine values and target Hb values (P = .0005). No statistically significant association was observed between adequate anemia control and type of dialysis (r= 0.106), time on dialysis (P = .28), sex (P = .224) and DM (P= 0.139).

20 YEARS’ EXPERIENCE OF PERITONEAL DIALYSIS IN SARAWAK, MALAYSIA
Vui Eng Phui1, Zhi Yang, Alex Koh2 and Hui Hong, Clare Tan3
1Sarawak General Hospital, Nephrology, Kuching, Malaysia, 2Sarawak General Hospital, Kuching, Malaysia and 3Sarawak General Hospital, Nephrology, Kuching, Malaysia

Background and Aims: Peritoneal dialysis is a modality of renal replacement therapy first introduced in the 1960s. In the event of the recent COVID 19 pandemic, peritoneal dialysis is gaining popularity due to the increased preference of home dialysis. Sarawak is the largest state in Malaysia with a population of more than 2 million. Unfortunately, 13% of households in the state are living in poverty. We present our experience with continuous ambulatory peritoneal dialysis (CAPD) for the past 20 years in a geographically and socioeconomically challenging region.

Method: Sarawak General Hospital is the centre of referral for Tenckhoff catheter insertion from other districts in Sarawak. This is a retrospective record review of all CAPD patients who were under our clinic follow up from 2001 to 2022. Data examined included patient’s demographic data, incidence of peritoneal dialysis related peritonitis and their outcome.

Results: All of the patients on CAPD were recorded by December of each year since we started our service in 2001 which shows a rising trend of patients on CAPD, with the highest in December 2022 at 399 patients. The number of patients with dialysis related peritonitis was also collected. Despite having more patients on CAPD, the number of peritonitis episodes per patient-year were in a decreasing trend. This was the result of the implementation of empirical first line intra-peritoneal antibiotics as part of the CAPD Peritonitis Management Protocol in 2015 and Decontamination Protocol in 2016.

Conclusion: Despite the headwinds of geographic and socioeconomic challenges, the number of patients on CAPD is on the rise. Over the years, peritonitis rate declined approaching to 0.2 episodes per patient-year. This was made possible with the introduction of local decontamination protocol and CAPD peritonitis management protocol, which helped improve the life expectancy and health of renal patients in the region.
ESTIMATION OF RENAL KT/V FROM 24-HOUR URINE VOLUME AND UREA DISTRIBUTION VOLUME IN PERITONEAL DIALYSIS

Matthias Zeiler¹, Gilda Fioravanti¹, Antonio Federico², Valentina Ramazzotti², Simona Silvestri¹, Giuseppe Fioravanti¹ and Stefano Santarelli²

¹Ospedale "C. e G. Mazzoni", Nephrology and Dialysis Unit, Ascoli Piceno, Italy and ²Ospedale "Carlo Urbani", Nephrology and Dialysis Unit, Jesi, Italy

Background and Aims: Residual renal function is an important factor in peritoneal dialysis (PD) regarding technical survival and implementation of incremental therapy schemes. The aim of the retrospective study was to develop an estimation formula of renal KT/V urea in PD based on urine output and anthropometric data.

Method: In 235 adult PD patients (151 males, 84 females, median age 66 years, median BMI 26.0, diuresis > 100 ml/day) urine output was registered together with anthropometric and lab data during the first peritoneal equilibration test. The dose of furosemide therapy was noted. Urea distribution volume calculated using the formula of DuBois. Measurement of urea in blood and urine was performed by a standard kinetic test with urease.

Results: 24-hour urine volume ranged from 100 to 3800 ml (median 1150 ml), similar in both sexes. Renal KT/V urea showed a significant linear correlation to daily urine volume ($r=0.78$, $p<0.01$) independent from sex and diuretic dose: renal KT/V urea = $5.116 + 0.0221 \times$ 24-hour urine volume (renal KT/V urea in liters/week, 24-hour urine volume in ml). Urea distribution volume varied between 24 and 60 liters (median 36.4 liters), and calculated renal KT/V ranged from 0.05 to 2.57 (median 0.84). Estimated renal KT/V, based on the before mentioned equation divided by urea distribution volume, correlated significantly to calculated renal KT/V ($r=0.75$, $p<0.01$). The goodness of fit analysis showed a mean absolute error of 0.24. The Bland-Altman Plot confirmed a tendency of over-estimation for renal KT/V < 1.0 and under-estimation for higher renal KT/V. A restriction of the analysis to 24-hour urine volume up to 1500 ml ($n=142$ patients, median age 69 years, BMI 25) resulted in an improvement of renal KT/V estimation (goodness of fit analysis: mean absolute error 0.20).

Conclusion: The estimation of renal KT/V in PD patients seems to be feasible utilizing 24-hour urine volume and anthropometric data.
METABOLIC PROFILING IN CHILDREN WITH END STAGE RENAL DISEASE ON PERITONEAL DIALYSIS: PRELIMINARY RESULTS OF AN ONGOING PRESPECTIVE STUDY

Antonia Kondou1, John Dotis1, Vasiliki Karava1, Olga Begou1, Anna Taparkou1, Eleftherios Panteris2, Helen Gika1, George Theodoridis1 and Nikoleta Printza1

1Greece, 2, Greece and 3, Greece

Background and Aims: Peritoneal dialysis (PD) is the main renal replacement treatment for children and adolescents with end stage kidney disease (ESRD). Peritoneal fibrosis is a major complication in long-term PD patients. Aim of the present study is to record the metabolic fingerprint of children on PD and to investigate its correlation with PD history and dialysis adequacy as well as the emergence of potential biomarkers that could detect early or predict peritoneal dysfunction.

Method: Serum samples from 15 patients undergoing peritoneal dialysis were analyzed. Two targeted LC-MS methodologies were used for the determination of 107 metabolites in total. The obtained results were compared based on demographic and clinical parameters, both before and after the dialysis procedure. Serum samples were further divided into subgroups, based on PD duration, creatinine clearance, sex, anuria. Regarding metabolic technologies used, all samples were analyzed by a hydrophilic interaction liquid chromatography coupled to mass spectrometry (HILIC-MS / MS) method previously developed and validated in our laboratory for the simultaneous determination of amino acids and their derivatives in biological fluids. Also, high flow analysis was carried out (LC-qTOF analysis – HPLC/MS). The evolution of this IP was favourable in 91.5% of cases with a response to antibiotics. 7% of episodes were relapsing of which five were during the first episode of IP. IP recurrence occurred in one patient. A catheter change was required over 16 episodes of IP, and hemodialysis sessions were necessary in 27 patients, temporary in 10 patients. The multivariate study identified the following predictive factors of IP: poor adherence to treatment (OR = 3.851; 95%CI: 1.369-10.837; P = .011) and weight less than 15 Kg (OR = 6.314; 95%CI: 1.333-29.897; P = .02).

Conclusion: Considering the high risk of peritonitis in children on PD, it is imperative to establish a primary prevention based on training of the caregivers.
Abstract

child’s caregivers and families. Continuous quality improvement program and PD technique are systematically reviewed in every peritonitis episode. Nutritional management of children prior to the start of PD is necessary to limit the risk of IP.

#5521
TENCKHOFF CATHERET EXIT-SITE INFECTION BY ACTINOMYCES ODONTOLYTICUS: A RARE CASE

Mariana Freitas, Bárbara Beirão Rodrigues, Jose Francisco, João Borges, Luis Oliveira, Rui Castro and Teresa Pinto Ribeiro Morgado
Centro Hospitalar de Trás-os-Montes e Alto Douro, Nephrology, Portugal

Background and Aims: Actinomyces odontolyticus is an anaerobic Gram-positive bacteria, which can be found among the commensal flora of the mouth and oropharynx. Diagnosis of infections due to this microorganism can be difficult because of its rarity, indolent course and lack of specific symptoms. Only one case of exit-site infection (ESI) due to Actinomyces odontolyticus in a patient on continuous ambulatory peritoneal dialysis (CAPD) has been reported. This work aims to report a case of ESI due to this rare agent.

Method: We present a case of Tenckhoff catheter ESI due to Actinomyces odontolyticus in a patient on CAPD.

Results: Case report: We report the case of a 26-year-old woman with a personal history of dyslipidemia, arterial hypertension and end-stage chronic kidney disease caused by Alport Syndrome in a CAPD program since April 2016. In June 2020, the patient presented an episode of refractory ESI due to methicillin-sensitive Staphylococcus aureus and was submitted to a shaving of the external cuff of the Tenckhoff catheter, with good subsequent evolution. The patient had no complications related to the catheter until April 2021, when she presented purulent drainage through the exit-site associated with erythema of the surrounding area. The consecutive exit-site swabs were negative. She underwent antibiotic therapy with ceftriaxone for 2 weeks with apparent resolution. However, in May 2021, the patient presents again erythema and purulent drainage and, at that time, a rare agent was isolated in the swab: Actinomyces odontolyticus with resistance to penicillin, amoxicillin, ceftriaxone and cefoxoxame. Given this isolation, the patient was treated with doxycycline 100mg every 12 hours for 4 weeks. The evolution was favorable with resolution of the infection and absence of recurrence for a 6-month follow-up. At the end of this follow-up time, the patient was transplanted.

Conclusion: Actinomyces odontolyticus is a bacteria of the commensal flora of the oral cavity and upper gastrointestinal tract, which can acquire pathogenicity in situations of impaired mucosal integrity and in immunosuppressed patients. Infections caused by this agent are rare and represent a diagnostic challenge due to its growth in an anaerobic environment and prolonged isolation time (5 days to 4 weeks). The immunosuppression conferred by chronic kidney disease and the history of external cuff shaving may have propitiated the infection by this rare opportunistic agent in our patient. The ESI presented for the patient in the previous month, which did not have an identified agent, was possibly caused by Actinomyces odontolyticus, but it was not isolated probably due to culture difficulties. The treatment of Actinomyces infections is generally conservative with 2 to 4 weeks of high-dose of intravenous penicillin, followed by 2 to 6 months of oral antibiotic therapy. In case of allergy, regimens with ceftriaxone, doxycycline, clindamycin or carbapenems are recommended. There is no consensus on the duration of treatment, with some authors recommending a minimum of 2 to 6 weeks. The mentioned patient was treated with 4 weeks of doxycycline according to the sensitivity test and the result was favorable, without the need to remove the catheter.

COGNITIVE DYSPUNCT ON AND ASSOCIATED RISK FACTORS IN PERITONEAL PATIENTS

Violeta Knezevic1,2, Tijana Azasevac1,2, Jelena Celic1,2, Dusan Bozic1,2, Vladimir Veselinov1,3, Lada Petrovic1,2
1 University of Novi Sad, Faculty of Medicine Novi Sad, Novi Sad, Serbia and 2 University Clinical Center of Vojvodina, Clinic for Nephrology and Clinical Immunology, Novi Sad, Serbia

Background and Aims: Patients with cognitive dysfunction (CD) are at greater risk of having a poor quality of life, hospitalization and mortality. Although CD in chronic kidney disease is current, most of the studies performed are cross-sectional. The aim of this cross-sectional study was to determine the presence of CD in the patients on peritoneal dialysis (PD) and to identify possible risk factors associated with CD.

Table 1: MMSE in relation with WTKt/V in PD patients.

<table>
<thead>
<tr>
<th>WTKt/V</th>

Method: We performed a study to evaluate the CD of 30 PD patients in our institution using the mini-mental state (MMSE), and a score of <25 was considered to indicate cognitive dysfunction. Demographic, clinical and laboratory parameters, adequacy of dialysis and drugs were analyzed. The statistical analysis included the chi-square test, t-test of independent samples, Mann-Whitney, and correlation.

Results: We evaluated 30 patients mean age of 57.27 years (SD=±12.086); 56.7% were male. About 66.7% of our patients were in marriage, 73.3% were not actively working. 13.3 had a lower level of education, and 56.7% lived in a city. The most prevalent comorbidities were glomerulonephritis and hypertension, both with 30.0%. 19 (57.6%) patients had average fast membrane characteristics. 15 of them (50%) had a daily dose of calcium phosphate binder >2g. MMSE test with a score lower than 25 was present in 36.7% of patients (IQR=4). Statistical analysis revealed a positive correlation between MMSE and weekly total Kt/V area index (WTKt/V), and the t-test of independent samples showed that patients with better MMSE score values have significantly higher average WTKt/V values (t=3.062, p<0.011).

Conclusion: MMSE test with a score less than 25 was present in 36.7% of patients and patients with better MMSE scores have significantly higher average WTKt/V values.

INCIDENCE, PREVALENCE, DEMOGRAPHIC PROFILE, AND CLINICAL OUTCOMES OF PERITONEAL DIALYSIS IN A TERTIARY MEDICAL CENTER IN THE PHILIPPINES

Keth Ivory Dela Cruz1 and Clarissa Arsolon2
1 Southern Philippines Medical Center, Department of Internal Medicine - Section of Nephrology, Davao City, The Philippines and 2 Southern Philippines Medical Center, Department of Internal Medicine - Section of Adult Nephrology, Davao City, The Philippines

Background and Aims: Chronic Kidney Disease (CKD) has emerged as a global public health burden. As one of the treatment options for CKD-5, peritoneal dialysis is underutilized, accounting for only 11% of the global distribution of renal replacement therapy (RRT). In the Philippines, PD accounts for only 4.2% [1] of all dialysis. This is perplexing because PD has several advantages over hemodialysis including better survival in the first few years of RRT, better survival of PD to HD than HD to PD [2], more cost-effective [3], can be done at home without sophisticated equipment, and feasible in remote areas. This study aims to characterize the incidence, prevalence, demographic profile, and clinical outcomes of the PD patients in our center to uncover strengths, weaknesses, and roadblocks for a stronger “PD First” program in the Philippines.

Method: Descriptive retrospective chart review of 146 PD patients of the Southern Philippines Medical Center from January 2018 to September 2022.

Results: There were a total of 146 adult patients enrolled to the PhilHealth PD Z-package from January 2018 to September 2022. Majority of the patients were aged 50-59 years old (20%), followed by 40-49 years old (19%), and 60-69 years old (19%), mostly male (57%). Predominant etiology of CKD-5 was Chronic Glomerulonephritis (41%), followed by Diabetic Nephropathy (30%), and Hypertensive Nephrosclerosis (19%). Incidence rate of PD was 44%, 22%, and 41% for 2019, 2020, and 2021 respectively. The prevalence rate of PD was 64%, 56%, and 59% for 2019, 2020, and 2021 respectively. The PD peritonitis rate was 1.25, 0.4, 0.24, and 0.3 episodes per patient year in 2018, 2019, 2020, and 2021 respectively. Out of the 146 PD patients, 41 (28%) are still on active PD, 1 (0.67%) underwent Kidney Transplantation, 38 (26%) had PD Technique Failure from peritonitis and catheter malfunction, and 66 (46%) expired due to death at home, sepsis, and acute coronary syndrome. Among those who expired, 22 (33%) were PD First and 44 (67%) were shifted from HD. There was a significant difference in the primary outcomes between those who were PD First and shifted from HD, with a p-value of 0.048.

Conclusion: PD First is infrequently practiced in our center. There is a significant difference in the number of those who were PD First, and those who were shifted from HD. There is a higher rate of mortality among those who were shifted from HD to PD compared to those who were PD First. PD- peritonitis is the number one cause of PD Technique Failure followed by issues
with the PD Catheter. To improve the mortality rate of our CKD-5 patients, it is recommended to do PD First, rather than HD to PD, while awaiting transplant.

REFERENCES

3. Bayani DBS, Almirol BJQ, Uy GDC. HCO3 after: 26.5 (24, 29) mEq/L. There was a statistically significant increase in the arterial HCO3- concentration between the values before and after the procedure [HCO3 before:25.4 (22, 28), HCO3 after:26.5 (24, 29) mEq/L; P = .023]. Likewise there was a statistically significant increase in BE with median values before the procedure 1 (-1.2, 2.9) and after the flushing 2 (-0.6, 3.8), P = .018. Even though there was a statistically significant increase in the bases expression of the acid base balance of the patients there wasn’t any statistically significant alterations in pH levels i.e. Alkalemia (pHbefore=7.41, pHafter=7.42 – P = .35) or pCO2 levels i.e. Compensatory Respiratory Acidosis (pCO2pH=40, pCO2pH+2=40 – P = .179) nor to the levels of ionized calcium.

Conclusion: Flushing of peritoneal cavity using peritoneal dialysis solution with bicarbonate as a buffer is safe and in this study was not correlated with the development of metabolic alkalosis.

THE EFFECT OF PERITONEAL CAVITY FLUSHING ON ACID BASE BALANCE OF PERITONEAL DIALYSIS PATIENTS
Marios Theodoridis, Stylianos Panagousou, Nikos Margaritis, Charalampos Dimitrakopoulos, Triantafyllia Bounta, Efthimia Mourvati, Evaggelia Charitaki, Konstantia Kantartzii and Elias Thodos
University Hospital of Alexandroupolis, Nephrology, Alexandroupolis, Greece

Background and Aims: Flushing peritoneal cavity with dialysis fluid with short time dwells it is a necessity in some cases for peritoneal dialysis patients. Such cases are overhydration with pulmonary congestion or peritonitis before the initiation of antibiotic treatment as an effort to reduce pain. The aim of this study was to investigate the effect of frequent exchanges with peritoneal dialysis (PD) fluid with bicarbonate as a buffer on acid base balance of peritoneal dialysis patients.

Method: This is a single center cohort study of 18 stable PD patients (m=10, f=8). Their median age was 57 (47, 71) years, their median PD duration was 33 (16, 89) months and they all fulfill the criteria for achieving adequacy targets [median Kt/V 2.17 (1.99, 3.3)] with good nutrition markers [median albumin levels 3.9 (3.6, 4) gr/dl]. A sample of arterial blood gas (ABG) was taken from the patients before the procedure and after full drainage of the peritoneal cavity. The procedure included 4 times flushing of 1000 ml of dialysis fluid with bicarbonate every 15 minutes. In the peritoneal cavity each time. At the end of the procedure a new blood sample for ABG was taken. We used PD solution with bicarbonate as a buffer (34 mmol/L). We estimated the alterations of pH, of bicarbonate (HCO3-), of pCO2, of Base Excess (BE), of ionized calcium ([Ca++]) and lactate (Lac) levels after the procedure [HCO3 before:25.4 (22, 28), HCO3 after:26.5 (24, 29) mEq/L; P = .023]. Likewise there was a statistically significant increase in BE with median values before the procedure 1 (-1.2, 2.9) and after the flushing 2 (-0.6, 3.8), P = .018. Even though there was a statistically significant increase in the bases expression of the acid base balance of the patients there wasn’t any statistically significant alterations in pH levels i.e. Alkalemia (pHbefore=7.41, pHafter=7.42 – P = .35) or pCO2 levels i.e. Compensatory Respiratory Acidosis (pCO2pH=40, pCO2pH+2=40 – P = .179) nor to the levels of ionized calcium.

Conclusion: Flushing of peritoneal cavity using peritoneal dialysis solution with bicarbonate as a buffer is safe and in this study was not correlated with the development of metabolic alkalosis.

Urology and Nephrology Center, Mansoura University, Mansoura, Egypt

Background and Aims: T-cell mediated immune response is crucial in kidney transplantation and plays an important role in allograft rejection. CD86 is a costimulatory molecule that participates in the regulation of T-cell lymphocytes activation. Single nucleotide polymorphisms (SNPs) located in this gene have been studied with inconsistent results. The aim of the study was to examine the association between (rs1129055:G/A) polymorphism in the CD86 gene and the development of acute renal allograft rejection among Egyptian patients.

Method: In this non-concurrent cohort study, we included a group of 50 kidney transplant recipients diagnosed by acute allograft rejection (AR) (which was defined by clinical diagnosis, elevated serum creatinine >30% of basal line in the absence of other pathology including infection, urinary tract obstruction, allograft artery stenosis or calcineurin toxicity and responded to treatment by immunosuppression and was confirmed by positive biopsy that was graded according to Banff classification) and another matched group of 50 kidney transplant recipients without AR and all of the 100 patients were genotyped by direct sequencing for CD 86 polymorphism (rs1129055:G/A) by TaqMan genotyping assay.

Results: The genotypic frequencies of CD 86 rs1129055 SNP in the acute rejection group were 72% GG, 28% AG and 0% AA while in the no rejection group it were 66% GG, 30% AG and 4% AA. The AA genotype and A allele at position +1057 in the CD86 gene were more frequent in patients without AR (4% and 23.4%, respectively) compared with those showing an AR (0% and 16.2%, respectively). The odds of acute rejection weren’t statistically significant either in dominant or recessive model (P = 0.665 and 0.475 respectively).

Conclusion: These results suggest that AA genotype and A allele of CD86 +1057G>A polymorphism may provide a nonsignificant protection against acute kidney allograft rejection among Egyptian patients.
Background and Aims: Young adulthood is a sensitive developmental period, and the psychosocial impact of kidney failure in this group is implicated in the observed high risk for transplant loss and death. In the Surveying People Experiencing young Adult Kidney failure (SPEAK) study we described differences in life-course outcomes, worse mental wellbeing and twice the likelihood of psychological disturbance among UK young adults with kidney failure (transplant or dialysis) compared to the general population. There have been no longitudinal studies investigating the natural history of these outcomes as young adults mature and get older. We undertook SPEAK-2 as a five-year follow-up study to address this.

Method: In this prospective observational study, respondents to SPEAK were invited to complete a revised online survey. PPI guided components of the original survey to amend. We analysed how psychosocial health had changed among respondents between studies using the paired t-test, Wilcoxon signed-rank test and McNemar’s test for continues parametric and non-parametric data, and binary data respectively. We compared responses to age-matched respondents of the Health Survey for England 2012 using regression. Responses were weighted to increase generalisability.

Results: We had 158 survey responses. The analysis of psychological health change over time is presented in Table 1. A greater proportion of participants had evidence of psychological morbidity (45% versus 24% in the original SPEAK study; p<0.001). They had inferior mental wellbeing (Warwick-Edinburgh Mental Wellbeing Scale [WEMWBS] β =-1.76; 95% CI, -3.27 to -0.25; P = .02). No differences were identified in domains including quality of life (EQ5D).

Key outcomes of the comparison to the age-matched general population are presented in Table 2. Respondents were less likely to be married or have children and were more likely to be living with their parents. They were almost 15 times more likely to report being unable to work due to health. Respondents had poorer quality of life and poorer mental wellbeing compared to the general population. They also five times greater odds of having psychological problems or mental ill health.

Conclusion: We report the first longitudinal study of the psychosocial health of a cohort of young adults with kidney failure as they age and mature. Over five years, we observed worse psychosocial health in terms of mental wellbeing and psychological morbidity. Respondents also lagged behind their peers in terms of life-course and psychosocial outcomes. Dedicated long-term follow-up is needed to clarify the extent and duration to which kidney failure in young adulthood impacts life participation and psychosocial health in the long term. Regardless, the degree of psychosocial ill health we have described warrants urgent increased support for this group.

**IMPACT OF KIDNEY DONATION ON PREGNANCY OUTCOMES: A RETROSPECTIVE ANALYSIS**

Anupma Kaul, Narayan Prasad and Dharmendra Bhanduaria
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Department of Nephrology, Lucknow, India

**Background and Aims:** More than 50% of living kidney donors are females with a significant proportion being in the childbearing age group. Recent data suggests risk of gestational hypertension, proteinuria and pre-eclampsia among pregnancies after kidney donation with a lower likelihood of full-term delivery.

**Method:** This retrospective study was conducted among females who donated kidney between (1997 - 2017) at a tertiary renal transplant centre in Northern India to assess for consequences of pregnancy outcomes among donors in terms of maternal and foetal outcomes.

Data of participants were collected using pre-tested semi structured questionnaire.

**Results:** 925 female kidney donors (1332 pregnancies) in the pre donation group while 45 females (48 pregnancies) in the post donation period were included. Mean age of first pregnancy, weight (kg) gain, proportion of history of pre-natal check-up and history of unrelated donation was statically significant among the post - donation group. The proportion of pre-eclampsia, gestational hypertension, gestational diabetes, post-partum hemorrhage was insignificantly higher among post donation group with higher preterm birth with low birth weight babies.

In Univariate analysis, Cesarean delivery, proteinuria and low birth weight <2500g were significantly associated with a decrease in CV events: Hazard Ratio (HR) [95% confidence interval (CI)]: 1.22 [0.73–2.03] (P = .435), HR: 1.12 [0.66–1.89] (P = .672), and HR: 2.78 [1.19–6.53] (P = .018), respectively. In the multivariable Cox model, diabetes mellitus was strongly associated with CV events (HR: 4.39 [2.79–6.90], p<0.001), and statin exposure was not (HR: 1.25 [0.78–2.03]). In a subgroup of KTRs exposed to statins after kidney transplantation but not before (n=314), the median [IQR] levels of LDL-c was 3.48 [2.89–4.08] mmol/L at starting statins and 2.74 [2.14–3.35] mmol/L after one year of statin exposure, i.e. a significant decrease of 0.74 [0.60–0.85] mmol/L (p<0.001). The median [IQR] levels of triglyceride was 1.99 [1.47–2.91] mmol/L when starting statins and 1.72 [1.20–2.50] mmol/L after one year of statin exposure, i.e. a significant decrease of 0.27 [0.17–0.42] mmol/L (p<0.001). There were no significant changes in HDL-c levels.

**Conclusion:** Despite an improvement in the lipid profile including a reduction of LDL-c and triglyceride levels, statin exposure was not associated with a decrease in CV events in a long-term KTR cohort. Other CV risk factors than dyslipidemia, such as diabetes mellitus, were more likely related to such events.

**Method:** 613 consecutive KTRs from a single-center cohort were retrospectively included between 2006 and 2019. Exposure to statins (indicated in primary or secondary CV prevention) and atherosclerotic CV events during the study period were comprehensively documented. The primary outcome was the incidence of CV events in all statin users compared to that of non-users, based on the Cardiovascular and Stroke Endpoint Definitions for Clinical Trials [2]. In this study, only atherosclerotic events were selected (peripheral vascular stenosis, stroke, myocardial infarction, angina pectoris and transitional ischemic attack). The secondary outcomes were the incidence of CV events (i) in KTRs using statins indicated in primary CV prevention and (ii) in KTRs using statins indicated in secondary CV prevention compared to that of non-users.

Cox proportional hazard models including statin exposure as a time-dependent covariate and fitted with inverse probability treatment weighting (IPTW) were used, as well as a multivariable Cox proportional hazard model.

**Results:** During a median [interquartile range (IQR)] follow-up period of 4.6 [2.7–10.0] years, CV events occurred in 88 KTRs: 48 (55.5%) KTRs had peripheral vascular stenosis, 24 (27.3%) had myocardial infarction, 12 (13.6%) had stroke, three (3.5%) had angina pectoris and one (1.1%) had a transitional ischemic attack. The incidence of CV events was 24.8 per 1000 person-years. In the Cox models fitted with IPTW, exposure to statins, regardless of the indication or indicated in primary and secondary CV prevention, was not associated with a decrease in CV events: Hazard Ratio (HR) [95% confidence interval (CI)]: 1.22 [0.73–2.03] (P = .435), HR: 1.12 [0.66–1.89] (P = .672), and HR: 2.78 [1.19–6.53] (P = .018), respectively. In the multivariable Cox model, diabetes mellitus was strongly associated with CV events (HR: 4.39 [2.79–6.90], p<0.001), and statin exposure was not (HR: 1.25 [0.78–2.03]). In a subgroup of KTRs exposed to statins after kidney transplantation but not before (n=314), the median [IQR] levels of LDL-c was 3.48 [2.89–4.08] mmol/L at starting statins and 2.74 [2.14–3.35] mmol/L after one year of statin exposure, i.e. a significant decrease of 0.74 [0.60–0.85] mmol/L (p<0.001). The median [IQR] levels of triglyceride was 1.99 [1.47–2.91] mmol/L when starting statins and 1.72 [1.20–2.50] mmol/L after one year of statin exposure, i.e. a significant decrease of 0.27 [0.17–0.42] mmol/L (p<0.001). There were no significant changes in HDL-c levels.

**Conclusion:** Despite an improvement in the lipid profile including a reduction of LDL-c and triglyceride levels, statin exposure was not associated with a decrease in CV events in a long-term KTR cohort. Other CV risk factors than dyslipidemia, such as diabetes mellitus, were more likely related to such events.

**Figure 1:** Association between statin exposure and cardiovascular events (Cox proportional hazard models with statin exposure used as time-dependent covariable).

**IPTW:** Inverse Probability of Treatment Weighting; **N:** number of patients exposed to statins.

* Variables included in the propensity score: age, BMI, sex, sedentarity, smoking, arterial hypertension, diabetes mellitus, prior statin exposure, immunological risk, preemptive transplantation, etiology of CKD, calcium, parathyroid hormone, LDL-c, HDL-c and triglyceride levels, use of corticoids, thyroglobulin, basiliximab, cyclosporine, MMF, everolimus, anticoagulants and antiplatelet agents.

**EARLY WEIGHT LOSS AFTER BARIATRIC SURGERY IN PATIENTS WITH ORGAN FAILURE OR TRANSPLANTATION**

Linda Moore1, Stephanie Yi1, Garth Davis1, Vadim Sherman1, Ashrith Guha2, David Victor3, Howard Huang4, Richard Knight1, A Gaber1, R Ghobrial1 and Nabil Tariq1

1 Houston Methodist Hospital, Surgery, Houston, United States of America, 2 Houston Methodist Hospital, Medicine, Cardiology, Houston, United States of America, 3 Houston Methodist Hospital, Medicine, Hepatology, Houston, United States of America and 4 Houston Methodist Hospital, Medicine, Pulmonology, Houston, United States of America

**Background and Aims:** Obesity is an epidemic that complicates global health and economies. Surgery for obesity (OS) is one effective treatment that results in significant weight loss. Patients with chronic organ failure who are obese undergo OS but it is unknown whether they achieve similar weight loss response as patients who do not have organ failure.

**Method:** Patient records of OS cases between May 2016 and June 2022 from a large healthcare system were examined to review weight changes after OS by whether the patient was a transplant patient or not. The proportion of excess weight lost was determined for 1-month, 3-months, 6-months and 1-year post OS. Non-parametric analyses were performed; p < 0.05 was considered significant.

**Results:** of 1,673 OS cases, the mean (SD) age was 47.6 (12.5) years, the majority were female (1,276, 76.3%), and 58% identified as Caucasian. Within this number, 92 patients were transplant candidates (n=50, 3%) or recipients (n=42, 2.5%). The transplant patients were older [51.5 (10.8) years vs 47.3 (12.6) years, P = .0008], had similar body weight [124.4 (22.5) kg vs 126.0 (27.2) kg, P = .8271] but a lower body mass index [42.6 (5.7) kg/m2 vs 45.1 (8.1) kg/m2, P = .0046] compared to patients who were not having a transplant. Transplant patients experienced different weight loss in the early post-operative period but similar weight loss after OS as non-transplant patients (Table 1 and Table 2).

**Conclusion:** Though early post-operative differences were noted in this study, patients with organ failure responded similarly to OS as patients without organ failure.

**PREDICTION OF REMAINING RENAL FUNCTION IN PATIENTS UNDERGOING RADICAL NEPHRECTOMY DUE TO RENAL TUMOUR MASS AND AFTER NEPHRECTOMY IN LIVING DONORS**

Andreja Figurek1, Valerie Luyckx2, Laura Hapuoja2, Daniel Schmid3 and Thomas Mueller4

1University of Zurich, Institute of Anatomy, Zürich, Switzerland, 2University of Zurich, Zürich, Switzerland, 3University Hospital Zurich, Clinic for Urology, Zürich, Switzerland and 4University Hospital Zurich, Clinic for Nephrology, Zürich, Switzerland

**Background and Aims:** Accurate assessment of renal function is of great importance in clinical practise, in particular in patients undergoing nephrectomy due to tumor nephrectomy or in potential living kidney donors. In both cases, residual renal function is dependent on the remaining nephron number and their function. A reliable prediction of the post-nephrectomy kidney function would be of great help to identify the patient with an increased functional risk. The aim of this study was to assess if the short-term kidney function after nephrectomy can be reliably predicted.

**Method:** We performed a retrospective study in 68 living kidney donors (LD-Nx) and 43 patients undergoing nephrectomy due to a renal tumour (Tu-Nx) between 1st of January 2011 to 31st of December 2015 at the University Hospital Zurich. Baseline serum creatinine was defined as lowest observed serum creatinine value before LD-Nx and Tu-Nx and was used for calculation of estimated glomerular filtration rate (eGFR) by the Cockroft-Gault (CG) and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formulas. The expected post-nephrectomy kidney function was calculated based on the formula (expected eGFRpost = 0.6 * eGFRpre + 8.7) described in detail in: (Prediction of kidney function after nephrectomy was performed by using the formulas previously established by our group [1]). Expected eGFR was calculated for CG and CKD-EPI formulas and expected serum creatinine was calculated from the expected eGFR based on CG formula. The expected kidney function was then compared to the observed kidney function based on lowest observed serum creatinine (LoObsSCr) during the first year after nephrectomy and the corresponding eGFR values for CG and CKD-EPI were calculated.

**Results:** Patients with nephrectomy due to renal tumour had significantly higher baseline serum creatinine levels compared to living donors (100±50 umol/l vs. 70±12 umol/l, respectively) with 35% having proteinuria, 58% hypertension and 14% diabetes mellitus. In addition Tu-Nx patients were significantly older and had a higher body weight. Living donors had a higher percentage of smokers (31%) compared to the other group. Predonation eGFR CKD-EPI was 71±23 ml/min/1.73 m² for Tu-Nx and 94±12 ml/min/1.73 m² for LD-Nx patients. Both groups showed an adaptive increase in kidney function calculated by eGFR CKD-EPI: 29% for Tu-Nx and 14% for LD-Nx. LD-Nx patients had less bias in prediction of post-nephrectomy kidney function (Table 1). Lowest observed serum creatinine after nephrectomy did not significantly differ between the groups. A significant correlation between expected and observed serum creatinine values, as well as between expected and observed eGFR post-nephrectomy, was seen in both groups of patients.

**Conclusion:** Despite older age, higher body weight and more comorbidities, patients with tumor nephrectomy show an adaptive increase in kidney function. Prediction of kidney function after nephrectomy is possible for both groups, however more accurate for living donor patients.

ANALYSIS OF IMMUNOSUPPRESSANT ADHERENCE, TREATMENT PREFERENCES AND NEEDS, AND MENTAL HEALTH DISORDERS IN THE POST-TRANSPLANTATION PERIOD

Juan Santacruz¹, Helena García-Llana², María Santana³, Rafael Selgas³, Carlos Jimenez³ and Elena Gonzalez²
¹Menysdial, Dialysis, Quito, Ecuador, ²La Paz University Hospital, Nephrology, Madrid, Spain and ³La Paz University Hospital, Madrid, Spain

Background and Aims: Medical treatment after kidney transplantation is not enough to assure optimal outcomes due to emotional factors that contribute on graft survival. To incorporate patient’s treatment preferences in clinical practice improves health outcomes. Few is known about treatment preferences and needs of kidney transplant population. The aims of the study were to quantify mental health disorders prevalence, immunosuppressive adherence, treatment preferences and needs of Spanish kidney transplant patients in post-transplantation period.

Method: Transversal-observational study in stable kidney transplant patients from one center in Madrid-Spain. Demographics, social-clinical variables, validated questionaries for anxiety, depression, stress, resilience, life satisfaction and quality of life related with health, and an ad-hoc survey of treatment preferences and needs were applied.

Results: A total of 116 patients were included, 25% had mental health pathology before transplant. Mental health disorders prevalence for depression, anxiety and stress were 26%, 27% and 23.3% respectively. Life satisfaction screening revealed only 29% of patients very satisfied with life. Patients with lower scores in mental health tests were significatively related with poor immunosuppressive adherence ($P = .004$). Treatment preferences and needs identified were how to improve physical condition (47%), information for anxiety and/or depression management (37%), and to receive psychological therapy from Nephrology Service (95%). See Table 1 and 2 for results.

Conclusion: Mental health disorders prevalence in Spanish kidney transplanted patients were high and had a negative impact in immunosuppressive adherence. This demands a biopsychosocial, interdisciplinary, focused on patient’s treatment preferences approach, individually and in groups from Nephrology Service.

KIDNEY TRANSPLANT-RELATED KNOWLEDGE AMONG SOUTH ASIAN COMPARED TO WHITE CANADIAN PATIENTS

Simran Jolly1,2, Shilpa Balaji1, Marzan Hamid1,3, Tanseem Patel1, Denzel Lodge1, Amy Waterman1 and Istvan Mucsi1

1Multi-Organ Transplant Program and Division of Nephrology, University Health Network, University of Toronto, Canada; 2McMaster University, Canada; 3Stanford University School of Medicine, United States of America and 4Houston Methodist Research Institute, Department of Surgery and J.C. Walter Jr. Transplant Center, Houston, United States of America

Background and Aims: Kidney transplant (KT) is the best treatment for many patients with kidney failure. However, patients from racialized communities are less likely to receive KT. Gaps in transplant-related knowledge may be one of the potential reasons for the observed inequities in accessing KT. Here we compare patient characteristics and KT-related knowledge between South Asian (SA) versus white Canadians with kidney failure using the “Knowledge Assessment of Renal Transplantation” (KART) questionnaire.

Method: Secondary analysis of data from a cross-sectional convenience sample of white and SA adults with kidney failure. Sociodemographic data, self-reported information about racialized status and KART score were collected through electronic data capture. The association between racialized status and participant demographics were assessed using ANOVA, Kruskal–Wallis test or chi squared test, as appropriate. The independent association between racialized status and KART scores was assessed by multivariable adjusted linear or multinomial logistic regression, with adjustment for immigration status, racialized status and KART scores was assessed by multivariable adjusted linear model.

Results: Among 578 participants (mean [SD] age: 57 [14] years, 64% male), 43% were white and 16% were SA. 84% vs 27% of SA vs white participants were immigrants. The Charlson Comorbidity Index score was greater for SA (p = 0.001). The median (interquartile range) KART score of white vs SA participants was 17 [6] vs 14 [7] (p < 0.001). A univariable linear regression model the KART score was significantly associated with SA status (B: -3.27 [(95% CI): -4.76, -1.77, p < 0.001]. This association remained significant after adjustment for potential confounding (B: -3.36 (95% CI): -5.05, -1.67, p < 0.001) (Table 1). 26% of SA vs. 41% of white participants scored in the highest tertile for KART score (p < 0.001) (Fig. 1). The relative risk ratio to be in the lowest KART tertile was 3.09 [95% CI: 1.49, 6.43] for SA compared to white participants in our final, adjusted multinomial model.

Conclusion: SA participants with kidney failure are commonly immigrants who have poorer KT-related knowledge compared to white participants. Our findings indicate the need to develop culturally relevant KT-related patient education for South Asian Canadian communities.

RENAI L RESERVE IN LIVING KIDNEY DONORS: THE HIDDEN ROLE OF OVERWEIGHT

Background and Aims: Renal reserve (RR) is the capacity to increase glomerular filtration rate (GFR) under certain stimuli such as obesity, hyperglycaemia, metabolic syndrome, etc. The importance of the presence or absence of RR is unknown. We investigated the prevalence and factors associated with RR in a group of living donors for renal transplantation.

Method: We investigated RR before donation in 52 living kidney donors. GFR was measured by iohexol clearance before and after the stimulation of RR by endovenous amino acid infusion. The presence of RR was defined as an increase greater than 10% of basal GFR. According with the presence or absence of RR, subjects were grouped in those without RR; with RR and using RR. The latter was defined as the lack of increase in GFR after stimulation in patients with GFR > 100 mL/min. GFR was unadjusted to body surface area (BSA). The characteristics of these three groups were evaluated.

Results: 13 (25%) had no RR, 24 (46%) had RR and 15 (29%) were using RR. Subjects without RR was predominantly female (92%) with lower BSA and BMI than those with RR or using RR (BMI: 22 ± 3 vs 28 ± 3 and 29 ± 4, p < 0.005); also had a lower GFR than the other groups (84 ± 10 vs 95 ± 14 and 131 ± 5.05,-1.67

Model 1: Racialized status (3 category: White, SA, Other) Model 2: 1 + Immigrant status (yes/no) Model 3: 2 + age, gender, marital status, education, employment status, OMI, Muslim/non-Muslim Model 4: 3 + transplant history, current modality, CCI
Survivals were compared between the two groups.

Data on demographics, comorbidities, immunologic properties and graft of pre-transplant dialysis treatment: Group A, Sina Hospital. KTRs were divided into two groups according to the duration of pre-transplant dialysis treatment (more than 10 years) on the outcomes of renal (KTRs) due to the donor shortage in Turkey. We assessed the effect of pre-transplant dialysis duration (more than 10 years) on the outcomes of renal (KTRs) due to the donor shortage in Turkey. We assessed the effect of pre-

Method: We retrospectively evaluated 480 KTRs who were grafted between 2000 and 2009 in Ankara University School of Medicine, Ibn Sina Hospital. KTRs were divided into two groups according to the duration of pre-transplant dialysis treatment: Group A, ≥10 years and Group B, <10 years. Data on demographics, comorbidities, immunologic properties and graft survivals were compared between the two groups.

Results: Group A included 60 patients and dialysis vintage was 288±60 months (Table 1). 420 patients in Group B had an average of 19 months period of dialysis treatment. While cadaveric transplantation was 78.3% in Group A, it was much lower in Group B (11.2%, p<0.001). Most of the patients were on hemodialysis treatment (95.0% vs. 58.3%, respectively, p = .001). Recipients’ age (P = .001), HLA mismatch number (P = .008) and PRA positivity (P = .001) were significantly higher in Group A. Although anti-human T-thymocyte globulin had been mostly chosen for induction therapy in Group A (p<0.001), almost all patients were under standard triple maintenance immunosuppression therapy. First year and late acute rejection rates were similar between two groups (p=1.000 and P = .407, respectively). Clinically important difference was demonstrated in graft loss, which was mostly seen in the ≥10 years dialysis group (Group A, 28.3% vs. Group B, 8.3%, P = .014). The 1-, and 5- years graft survival rates were 91.4%, and 81.3%, respectively, in Group A and 97.4%, and 93.4%, respectively, in Group B (P = .029 and P = .014, respectively). Patient loss was significantly higher in Group A (Group A, 28.3% vs. Group B, 14.3%, P = .018).

Conclusion: We demonstrated that pre-transplant dialysis duration for more than 10 years has adverse effects on post-transplant graft and patient outcomes, accompanied by high immunological risk. Updates of organ allocation system considering sensitized candidates and strategies to expand donor pool and donation rates are needed to reduce waiting times on dialysis.

PHENOTYPIC CHANGES OF LYMPHOCYTES FOLLOWING RENAL TRANSPLANTATION

Xaralampos Vagiotas1,2, Georgios Lioullos2, Eleftherios Moysidou3, Aliki Xochelli5, Efstratios Kasimat12, Georgios Tsoulfas2, Aikaterini Papagiannis1, Asimina Fylaktou1 and Maria Stangou3

1School of Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece, 2School of Medicine, Aristotle University of Thessaloniki, Renal Transplant Unit, Thessaloniki, Greece, 3School of Medicine, Aristotle University of Thessaloniki, Department of Nephrology, Renal Transplant Unit, Thessaloniki, Greece and 4Hippokration General Hospital, Department of Immunology, National Histocompatibility Center, Thessaloniki, Greece

Background and Aims: Phenotypic changes in lymphocytes have been described following renal transplantation (RT), including both CD4 and CD8 subpopulations. The present work aims to prospectively assess T lymphocyte phenotypic alterations, after RT and compare differences between deceased (DR) and living (LR) donor recipients.

Method: One hundred six RTRs were included in the study, 78/106 (74%) DR, age 52.5(15) yrs and 28/106 (26%) LD, 35(21) yrs. Lymphocytes, CD4, CD8, CD4CD28null, CD8CD28null, CD16+CD56+ (NK) and CD4+CD25+FoxP3+ (Tregs) were evaluated at peripheral blood, by flow cytometry, at certain time points: RT and 3, 6, 12 months (T0, T3, T6, T12, respectively).

Results: During follow up, at T3, T6, T12, eGFR was 61(23.6), 62.2(31.1), 63.5(23.9)ml/min/1.73 m2, p=NS and 91(24.8), 61(25.3), 62(22.7), p=NS, in DR and LR group, respectively. eGFR showed no significant difference between DR and LR at any time point. At any time point, T0, T3, T6, 12,

lymphocytes were significantly increased in DR compared to LR groups, P = .001, p <0.0001, P = .002, p <0.0001, similarly CD4, P = .001, p <0.0001, P = .001, p <0.0001, and CD8 cells, P = .002, p <0.0001, P = .005, P = .006, respectively. Tregs were increased at T0, T3, T6, not at T12, p <0.0001, p <0.0001, P = .001, p = .1, respectively. At this point, Tregs were increased in RTRs with eGFR>50ml/min/1.73 m2, 20.3(9.3) vs. 27.2(18.6), P = .03. CD4CD28null, CD8CD28null cells did not change during follow up, and there was no difference between two groups at any time point.

Conclusion: Immune profile was improved in both groups, DR or LR, however a significantly better effect managed in LR, although elimination of CD28 molecule could not be restored. Interestingly, Tregs were associated only by renal function one year following RT.

ASSESSMENT OF THE PSYCHOLOGICAL EXPERIENCE OF KIDNEY TRANSPLANT PATIENTS DURING THE COVID-19 PANDEMIC

Sara Mazighi, Salma Naouaoui, Mariam Chettati, Wafaa Fadili and Inass Laoud1

Marrakesh, Nephrology, Hemodialysis, Marrakesh, Morocco

Background and Aims: The coronavirus (COVID 19) pandemic has caused a major health crisis, and quarantined half of the world's population, therefore it contributed to the appearance or aggravation of mental distress such as anxiety, depressive disorders and deterioration of the quality of sleep especially in the immunocompromised population and especially in the kidney transplant patients. Among the causes of these disorders are the risk of infection and the relatively high mortality rate associated with this virus. The aim of our study is to investigate anxiety and depression scores in renal transplant patients during the COVID 19 pandemic and compare them to those of the general population to highlight the impact that the pandemic has had on this vulnerable population.

Method: This is a descriptive and analytical case-control study of a group of 113 patients divided into 2 groups: group of kidney transplant patients and that of the general population. A questionnaire collecting sociodemographic data was used. Anxiety symptoms were assessed by the GAD anxiety scale. Depressive symptoms were assessed using the Beck's scale abbreviated.

Results: In our study, the rates of anxiety and depression in the general population group were around 33.3% and 18.3% respectively. This rate was significantly higher in subjects with previous psychiatric history. These rates were higher in women with an anxiety rate of 18.3% versus 15% in men and a depression rate of 11% in women versus 7% in men and were significantly higher in subjects with previous psychiatric history. In the group of kidney transplant patients the rates of anxiety and depression were high compared to the general population, with a rate of anxiety at 66% and depression at 26.4% (p<.001).

Conclusion: This study raised the major negative impact of the covid 19 pandemic on the increase of psychiatric disorders in this at-risk population compared to the general population. This requires a multidisciplinary and adapted management of these vulnerable patients, associating a joint nephrological and psychiatric follow-up in order to preserve their quality of life and their mental health.

LAPAROSCOPIC Nephrectomy in patients with autosomal dominant polycystic kidney disease

Olimkhan Sharapov1,2, Sherzod Abdullaev2,3

1Republican Specialized Scientific Practical Medical Center of Nephrology and Kidney transplantation, Adult and children nephrology, Tashkent, Uzbekistan; 2Tashkent Pediatric Medical Institute, Nephrology and hemodialysis, Tashkent, Uzbekistan and 3Republican Specialized Scientific Practical Medical Center of Nephrology and Kidney transplantation, Scientific department, Tashkent, Uzbekistan

Background and Aims: At the present, discussions continue on the indications and timing of performing kidney nephrectomy in patients with autosomal dominant polycystic kidney (ADPK) disease who are on the waiting list for kidney transplantation. Large sizes of kidneys, traumatic access, accompanying these operations cause a high incidence of postoperative complications, mortality and aggravate the severity of patients. The aim of the present study was to find the preferred algorithm for preparing patients for kidney transplantation.

Method: The results of the nephrectomy of polycystic kidneys were analyzed in 28 patients (mean age 49±1.5 years, 16 men, 12 women), which were conditionally divided into two groups. The first group included 13 patients (46.4%) with open surgery using median laparotomy and lumbotomy, in the second group - 15 (53.6%) - laparoscopic nephrectomy. Surgical interventions for patients in both groups receiving renal replacement therapy dialysis, performed according to emergency and planned indications.

Results: The average duration of laparoscopic and open surgical interventions was 149±14 and 132±15 min, respectively. The maximum size of deleted polycystic-altered kidneys in the first group was 21.3±4.21 cm, in the second group it was 20.5±3.3 cm. The incidence of postoperative complications in the 1st and 2nd groups was 6 cases (46.1%) and 2 cases (13.3%), respectively. There was one fatal outcome (7.69%) in the 1st group as a result of septic complications. the average postoperative bed-day in the first group was 12-13 (12.7 ± 1.1), in the second - 8-9 (8.6±0.5). Patients after laparoscopic interventions are activated on the 2nd-3rd day (2.8±0.14), after open operations - on the 4th-5th (4.43±0.32).

Conclusion: The incidence of postoperative complications after laparoscopic nephrectomy in patients with ADPK does not exceed 13.3%. The use of laparoscopic technologies makes it possible to expand the possibilities of using nephrectomy for the treatment and preparation of patients with polycystic kidney transplantation.

#3003

IMPACT OF FULL CORRECTION OF HEMOGLOBIN AMONG POST-TRANSPLANT ANEMIC KIDNEY TRANSPLANT RECIPIENTS: A PROSPECTIVE RANDOMIZED CONTROLLED TRIAL

Torki Aloтаib1, Oasma Ashhy Ahmed Gheith1,2, Ayman Maher Nagib1,2, Medhat Abdulhalim1, Hasaneen Hasaneen Ahmed Aboaty Aboaty1, Tarek S.H. Mahmoud3, Prasad Nair1, Hany Adel1, Ahmed Mossaad1, Ahmed Atta1 and Mohamed Abdullahm1

1Hamed Alesa Organ Transplant Center, Kuwait, Nephrology, Kuwait, Kuwait and 2Mansoura University, Nephrology, Mansoura, Egypt

Background and Aims: Several studies have shown that post-transplant anemia (PTA) might be associated with increased mortality and decreased graft survival and de-novo congestive heart failure. So we aimed from this prospective randomized controlled study to assess the impact of full correction of PTA on the cardiovascular system of renal transplant recipients receiving erythropoietin stimulating agents (ESA).

Method: We recruited 247 kidney recipients with stable graft function in this RCT with 2 groups according to their target hemoglobin (11-12 g/dl, group 1, n=183) and (13-15 g/dl, group 2, n=64). After correction of deficiencies, the target hemoglobin was achieved using ESA. All patients were followed up clinically and Laboratory and radiologically for 12 months.

Results: Diabetic nephropathy was the main cause of ESKD in group 1. The studied groups were comparable regarding pre-transplant co-morbidities. Most patients received thymoglobulin as induction then cyclosporine based maintenance immunosuppression. We did not find any significant difference between the two groups concerning post-transplant diabetes, BK viremia or malignancies and even cardiovascular events (TIA, stroke, ACS), (p>0.05).

Group 1 showed higher mean blood pressure (P = .003), lower LV internal
Conclusion: Full correction of PTA is associated with stabilized cardiac dimensions indices without any significant cardiovascular comorbidities.

#5364
LOW DOSE VALGANCICLOVIR AS A PRE-EMPTIVE THERAPY IS EFFECTIVE FOR CYTOMEGALOVIRUS INFECTION IN KIDNEY TRANSPLANTATION: A SINGLE-CENTER EXPERIENCE

Jin Seok Jeon, Haekyung Lee, Hyoungnae Kim, Soon Hyo Kwon and Hyunjin Noh

Soonchunhyang University hospital, Department of Internal Medicine, Seoul, Rep. of South Korea

Background and Aims: Pre-emptive therapy, screen for and treat asymptomatic cytomegalovirus (CMV) viremia, is an important preventive strategy for CMV disease in kidney transplant (KT) recipients. Oral valganciclovir is the most commonly used as preventive strategy. However, the optimal dose and treatment duration of valganciclovir remains elusive.

Method: We retrospectively evaluated the efficacy and toxicity of low-dose of oral valganciclovir (250mg twice daily) as pre-emptive therapy in KT recipients who underwent KT between January 2015 and December 2021. CMV viral load was measured by polymerase chain reaction. Pre-emptive therapy with valganciclovir was applied for 2 weeks.

Results: of 33 kidney transplant recipients who received pre-emptive CMV therapy with valganciclovir (55 therapy cases), 32 (97.0%) were CMV seropositive except 1 patient who had no related information. Thirty-two (311.24 – 826.25), whereas 4420.00 (2535.00 – 137450.00) in patients who underwent KT between January 2015 and December 2021. CMV viral load was measured by polymerase chain reaction. Pre-emptive therapy with valganciclovir was applied for 2 weeks.

Conclusion: These results suggest that pre-emptive therapy with low dose oral valganciclovir for 2 weeks can be successfully used for preventing CMV disease among KT recipients with low-level CMV viremia. Further research is needed to replicate these findings in larger samples and assess long-term outcomes.

#6369
RESULTS OF KIDNEY TRANSPLANTATION IN PATIENTS WITH LOW MFI PREEMPTED DONOR SPECIFIC ANTIBODIES

Maria Paola Salerno1,2, Patrizia Silvestri2, Natalia Romina Zanoni2 and Franco Citterio3

1Italy and 2Roma, Italy

Background and Aims: Preempted DSA at transplantation, significantly increase risk of antibody-mediated rejection (ABMR). While pre-existing positive DSA with concomitant positive cross-match is a general contra-indication to kidney transplantation, DSA presence with negative cross-match is still a controversial topic. The presence of DSA with Mean Fluorescence Index (MFI) up to 3,000 and a negative cross-match is valued as a contraindication to transplantation and is widely accepted. In some transplant centers the chance of transplantation is also offered to DSA positive patients, with MFI up to 5,000. Aim of this study was to analyze graft and patient survival, acute cellular rejection, humoral rejection, renal function and side effects in kidney transplant recipients (KTR) with positive DSA (MFI up to 3,000) and negative cross-match.

Method: Nineteen pts (age 53+/−11) with chronic renal failure on chronic hemodialysis treatment (8+/−6 years) received a kidney transplant between May 2017 and December 2020. Median PRA was 66%; 100% pts had DSA with average MFI 2122 (min 1039, max 3779). As immunosuppressive therapies all pts received induction with Thymoglobuline plus Rituximab, followed by maintenance immunosuppression with Tacrolimus, MofetilMycoFenolate and Steroids. All pts were on periodic follow up in our Transplant Clinic. Median follow up was 26.5+/−14.4 months. Results were compared to a concomitant KTR group DSA and crossmatch negative.

Results: After 2y follow-up, 17/19 pts are alive (95.8%), one patient died (1/19, 5.2%) after treatment for ABMR. Three patients returned to dialysis treatment (15.8%) during the first year post-tx, because of: PNF 1pt; irreversible ABMR rejection 2 pts. One other patient had reversible ABMR. Cumulative one year graft survival was 79% and the cumulative incidence of ABMR was 15.8%. Average 2 years follow-up creatinine was 1.46+/−0.88 mg/dl, median 2 year GFR was 51+/−25 ml/min. Comparing the matched control group (19 pts DSA and crossmatch negative) 2 years patient survival, graft survival and GFR, acute rejection were not significantly different. Incidence of acute rejection was higher in the DSA positive group (16% vs 0%), as well as graft loss (21% vs 12%).

Conclusion: Our data suggest that low dose Thymoglobuline plus Rituximab induction allow kidney transplantation in recipient with high PRA (69%) and positive DSA with low MFI (< 3,000), with higher risk of acute rejection, and graft loss.

#6833
ARE KT RECIPIENTS TAKING THEIR IMMUNOSUPPRESSANT MEDICATION? PRELIMINARY EVIDENCE FROM A SUPER-SPECIALIZED TRANSPLANT CENTRE IN SUB-SAHARAN AFRICA

Olaelek Olatiise1, Michael Muoka2, Stephen Asaolu2, Adebowale Adekoya1, Adaku Olatiise1 and Adeboyega Faponle1

1Zenith Medical and Kidney Centre, Department of Medicine, Abuja, Nigeria, 2Zenith Medical and Kidney Centre, Department of Clinical Research, Abuja, Nigeria and 3Lagos State University Teaching Hospital (LASUTH), Ikeja, Nigeria

Background and Aims: Immunosuppressant non-adherence is a leading cause of preventable renal allograft dysfunction, rejection and graft loss. The barriers to immunosuppressant adherence as well as associated risk factors of non-adherence vary across studies in different locations. This study aimed to investigate the prevalence of immunosuppressant non-adherence among adult kidney transplant recipients and identify barriers to adherence in a renal transplant cohort.

Method: A cross sectional survey was conducted using the Basel Assessment of Adherence to Immunosuppressive Medications Scale (BAASIS), the Immunosuppressant Therapy Barrier Scale and the Beliefs about Medicines Questionnaire. Adherence was defined according to the BAASIS, with barriers to adherence and beliefs about medicines compared between the two groups. Participants were recruited from the out-patient clinic at Zenith Medical and Kidney centre. An advert for the study was placed in consultation rooms and patients were approached to join the study when they attend appointments. IBM SPSS Statistics for Windows, Version 23 (Armonk, NY: IBM Corp) was used for data analysis.

Results: The rate of non-adherence was 50.7% out of 67 kidney transplant recipients attending outpatient clinic. There were statistically significant associations between non-adherence and occupation (P = 0.049). Participants who are on MMF were more adherent than those on sirolimus (97.0% vs 79.4% and 0.0% vs 8.8%) and this difference is statistically significant (P = 0.038). Also, participants who have had one or more post-transplant hospital admission are more non-adherent when compared with those that have never been admitted (P = 0.02). The only significant barrier to adherence was when patients travelled out of town (P < 0.005). Adherence was not associated with patients’ belief about their medicines.

Conclusion: Interventions aimed at ensuring constant access to immunosuppressant drugs and those based on habit forming may significantly improve adherence in this cohort.

E4 - COMPLICATIONS IN TRANSPLANTATION

#2649
INFECTIOUS COMPLICATIONS AFTER KIDNEY TRANSPLANTATION IN RELATION TO INDUCTION IMMUNOSUPPRESSIVE THERAPY

Matej Vnucák, Karol Grafiáčok, Monika Beliančinová, Patricia Kleinová and Ivana Dedinská

University Hospital Martin, Transplantation Center, Martin, Slovakia

Background and Aims: Infections are the most common non-cardiac cause of death after kidney transplantation (KT). The main goal of immunosuppressive therapy is to find a balance between the low incidence of acute rejection and infectious complications.

Method: We conducted a retrospective, monocentric analysis of transplant patients at the Transplant Center University Hospital Martin from 2011 to 2020 with various induction immunosuppressive therapies. We monitored the incidence of infections in terms of etiology, localization and severity at different intervals after KT.
Results: Our study included 39 patients on induction therapy with basiliximab to whom we paired 39 patients with induction therapy with thymoglobulin based on gender and age, in total our population consisted of 78 patients (56 men, 22 women), the mean age was 45 years. In the group of patients with induction therapy with thymoglobulin, we noted a higher proportion of fungal (P = 0.0409), urogenital infections (P = 0.0384), sepsis (P = 0.0497) and leukopenia (0.0384) from 1st to 6th month after KT, higher incidence of skin infections (P = 0.0218) and serious infections requiring hospitalization (P = 0.0269) from 6th-12th months to TO. On the other hand, in the basiliximab patient group, we identified a higher incidence of acute humoral and cellular rejection (P = 0.0218) after 6 months of TO. From the perspective of recurrent infections, in the Thymoglobulin induction group, we noted a higher incidence of infections by localization, etiology and severity. Risk factors for recurrent bacterial infections from 1st to 6th month after KT are: history of respiratory infections, in the Thymoglobulin induction group, we noted a higher incidence of rejection (P = 0.0218) from 6th-12th months to TO. On the other hand, in the basiliximab induction therapy with basiliximab have a higher risk of developing acute rejection. Therefore, it is essential to identify risk groups of patients benefiting from milder or more intensive inductive immunosuppressive therapy without a concomitant increased risk of infectious complications or acute graft rejection.

Conclusion: Patients on inductive immunosuppressive therapy with thymoglobulin are at a higher risk of recurrent, multidrug-resistant and severe infections after KT compared to induction with basiliximab with identical maintenance immunosuppressive therapy. On the other hand, patients on induction therapy with basiliximab have a higher risk of developing acute rejection. Therefore, it is essential to identify risk groups of patients benefiting from proatherosclerotic infectious complications or severe graft rejection.

Predictors of Kidney Function decline in Living Kidney Transplantation Donors

Predictors of Kidney Function decline in Living Kidney Transplantation Donors

**Lada Trajcheska 1, Irena Rambabova- Bushljetik 2,3, Igor Nikolov 2, Galina Severova- Andrevska 1, Stefan Filipovski 1, Zhaklina Shterjova- Markovska 1, Aleksandra Canevska Taneska 1, Mimoza Milenkova 1, Adriana Spasovska Vasilova 1 and Goce Spasovski 2**

1University Clinic of Nephrology, Transplantation, Skopje, Republic of North Macedonia, 2Skopje, University Clinic of Nephrology, Skopje, Skopje, Republic of North Macedonia, 3University Clinic of Nephrology Skopje, Transplantation, Skopje, Republic of North Macedonia and 4University Clinic of Nephrology Skopje, Transplantation, Skopje, Republic of North Macedonia

**Background and Aims:** After nephrectomy kidney transplant donors lose 50% of their renal mass. Shortage of donors and long waiting list for deceased donor transplantation expanded the living donor criteria. The aim of this study is to identify pretransplant donor related factors associated with renal function decline.

**Method:** We retrospectively studied LDKT donors from one transplant center in the period 2013 -2022. Data was retrieved from medical history charts and national electronic database system. Demographic characteristics as age, gender and relation to the recipient, patients preference to donate the kidney with higher measured split GFR, the presence of diabetes, hypertension, hyperlipidemia and BMI >30 kg/m² were analysed. Estimated GFR by CKD EPI was notified prior donation, one and two years afterwards. In a multivariate regression analysis the reduction ratio of CKD EPI was explored as dependent variable.

**Results:** We studied 121 donors. The average age at time of transplant was 59.18 ± 10.99 years. Donors' average eGFR was 91.53 ± 18.62 ml/min. Donor's age and eGFR were significantly correlated (r = -0.529). Male donors were 73 (60%), 11 (9%) were unrelated to recipients, 9 (7%) had BMI > 30, 17 (14%) diabetes, 53 (44%) hypertension 5 (4%) hyperlipidemia, and 65 (52%) had more than one comorbidity combined. Eight of donors (7%) decided to donate the better kidney. CKD EPI declined to 67.18±18.62 ml/min at first and 66.01±21.29 ml/min at the second year. The RR of 24.53 ± 20.60 % and 27.62±18.76% raised on yearly bases, respectively. In the univariate analysis of the GFR declination at the first year BMI > 30 kg/m² was associated with higher reduction of GFR (β=0.318, P = .003). At the second year the presence of diabetes emerged as worsening factor of GFR (β=0.227, P = .034) and BMI> 30 kg/m² kept its significance (β=0.426, P = .000). All the other parameters showed no significant associations to the GFR decline. In the multivariate analysis BMI> 30 kg/m² remained as most powerful predictor at 12 months reduction of eGFR.

**Conclusion:** Patients with diabetes and especially with obesity are at higher risk of rapid decline in kidney function after kidney donation. Careful assessment prior kidney donation should weight the risks.
Method: This is a retrospective, monocentric and observational cohort study. The study population consists of patients that underwent kidney transplantation in a single Kidney Transplant Unit from 1978 to 2012 and still in follow-up within the same Unit with a functioning graft. Data were extracted from the Hospital digital medical records after informed consent has been obtained. We analysed renal function at 5-year intervals from discharge to the last evaluation using eGFR calculated with the CKD-EPI formula. Data on demographic characteristics, comorbidities, immunosuppressive therapies and complication (divided as infectious, immunological and malignancy) has also been evaluated.

Results: We enrolled 332 patients with a mean follow-up of 17.9 ± 6.5 years, of whom 101 (30.4%) with a follow-up > 20 years. Figure 1 shows the trend of renal function during the follow-up years. In Table 1 are reported the comorbidities and immunological, infectious and neoplastic complications. 46 (14.5 %) patients underwent a “for cause” kidney biopsy. The main finding, with 62% was transplant glomerulopathy/interstitial fibrosis and tubular atrophy (TG/IFTA) with a mean post-transplant onset of 12.8 years (± 6.1), 9% of rejection findings with a mean time to onset of chronic rejection of 18 years (±8) and 1.3% of biopsied patients received a diagnosis of recurrence with a mean onset of 10.8 years (±4.4). 36.1% of the patients experienced at least one neoplasm with an average post-transplant onset time of 13.4 (±7.7). Infectious complications occurred in 36.1% of the transplanted patients.

Conclusion: This study provides an exhaustive overview of the characteristics and clinical complications in a “real life” experience with long survivor kidney transplants with the aim to better understand the needs and problems of this peculiar population in order to guide clinicians in a more targeted management.

AN UNEXPECTED CASE OF 2,8-DIHYDROXYADENINE NEPHROPATHY AFTER KIDNEY TRANSPLANTATION RELATED TO

Figure 1: Evolution of renal function (eGFR).
NEW VARIANTS OF ADENINE PHOSPHORIBOSILTRANSFERASE GENE

Fabiana Brigante1, Giada Tortora2, Roberta Mazzucchelli2, Maria Ilaria Moretti1, Mauro Valente1, Valentina Viola2, Marco Moretti3, Emilio Balestra1, Domenica Taruscia1 and Andrea Ranghino1

1AOU delle Marche, Nephrology, Dialysis and Renal Transplantation Unit, Ancona, Italy, 2AOU delle Marche, Genetics and Rare Diseases Unit, Ancona, Italy, 3AOU delle Marche, Department of Biomedical Sciences and Public Health, Section of Pathological Anatomy, Ancona, Italy and 4AOU delle Marche, Laboratory Medicine, Ancona, Italy

Background and Aims: Adenine phosphoribosyltransferase (APRT) deficiency is a rare autosomal recessive disorder of the purine metabolism which results in the conversion of adenine into 2,8 dihydroxyadenine (DHA) due to the activity of the xanthine oxidoreductase (XOR). Patients affected by APRT deficiency who do not receive inhibitors of XOR may develop 2,8-DHA nephropathy that might progress to end-stage kidney disease (ESKD) with the need of kidney transplant. The high rate of misdiagnosis of 2,8-DHA nephropathy in native kidneys could lead to the failure of kidney graft in transplanted patients affected by APRT deficiency.

Method: Here, we report the case of a female, 63-years old patient with ESKD of unknown cause on regular hemodialysis treatment from 2018 after a period of three years on peritoneal dialysis, who underwent kidney transplantation in our Center in 2022. Her medical history showed a metabolic syndrome. She did not experience episodes of renal colic whereas family history reported a brother affected by frequent renal colic of unknown cause. In March 2022, she underwent kidney transplantation from a deceased death brain donor. Induction therapy includes basiliximab, tacrolimus, mycophenolic acid and steroids. Due to the persistence of delay graft function, ten days after kidney transplantation an allograft biopsy has been performed. The histological examination revealed tubular damage surrounded by inflammation cells and intratubular crystals in the renal cortex. The crystals were reddish brown tinged in hematoxylin and eosin stain and were birefringent under polarized light. Fig. 1 A, B, so they were strongly related to the hypothesis of DHA crystals. Consistently, the urinalysis showed yellow-brown crystals of DHA. Thus, a genetic analysis of APRT gene has been performed showing two novel heterozygous variants c.388_397p.(Leu130ValfsTer4) and exon 3 deletion, expected pathogenic. The patient was treated with bolus of methylprednisolone (4mg/kg alternate to 50 mg) and a therapy with febuxostat 80 mg/die was started to reduce the amount of plasma DHA. In addition, based on our previous experience of recurrence DHA nephropathy after transplantation, we treated the patient with six consecutive hemodiafiltration (HDF) sessions without ultrafiltration, to promptly remove the serum DHA avoiding their precipitation in the graft while waiting for the lowering effect of febuxostat.

At discharge the patient showed an increase of the urine output not associated with a complete recovery of kidney function (sCr 3.88 mg/dl, uric acid 1.6 mg/dl), so two other hemodialysis treatments were performed in the next two weeks.

Results: At present, almost one year after kidney transplant, the patient is doing well and the graft function is stable with a sCr of 1.6 mg/dl without significant presence of DHA crystals in the urine.

Conclusion: In conclusion, we find out an unexpected recurrence of 2,8-DHA nephropathy due to novel expected pathogenetic variants of APRT gene in patient without medical history of kidney stones successfully treated with steroid, febuxostat and hemodiafiltration.

RETROSPECTIVE EVALUATION OF THE PREVALENCE OF DIABETES MELLITUS IN A SINGLE CENTER RENAL TRANSPLANT COHORT

Carlo Maria Alfieri1,2, Paolo Molinari3, Elisa Cicero1, Edoardo Campioli1, Anna Regalia1, Maria Rosaria Campise1, Donata Cresseri1, Simona Verdesca1, Evaldo Fav1,2, Giuseppe Castellano1,2

1Fondazione IRCCS Ca Granda Ospedale Maggiore Policlinico, Italy and 2University of Milan, Milano, Italy

Background and Aims: Post-transplant diabetes mellitus (PTDM) might impact significantly in renal transplant (RTx) and RTx patients (RTxps) outcome. In this study we evaluated: 1) the prevalence of diabetic patients who access the RTx 2) the incidence of PTDM and 3) the most related factors for the development of diabetes after RTx.

Method: We retrospectively studied 522 RTxps transplanted in our Unit between January 2004 and December 2014. Each patient underwent: 1) to a collection of remote and pathological anamnesis and complete physical examination and to routine and specific clinical and biochemical determinations at 1 (T1), 6 (T6) and 12 (T12) months after RTx. At six months of RTx, the Oral Glucose Tolerance Test (OGTT) was performed.

Results: The age of RTxps was 48±12 years. Patients with glucose metabolism abnormalities were significantly older, without differences in gender. Inpatients with PTDM (12.6%), cyclosporine was used more than tacrolimus, and higher doses of steroids at T1 and T6 were prescribed. They had a worse general metabolic and glucose (HOMA index, glycaemia and HbA1c) status than normoglycemic. of note, no differences in 25-(OH)-D and in the other mineral metabolism parameters were found. In multivariate analysis, we found that age at transplant (OR 1.28 for 5 years older) (p = 0.006), BMI at T1 (OR 1.22 for 2 kg / m2 more) (p = 0.01) and the dose of steroid prescribed during the

Abstract

## Figure 1: Allograft kidney biopsy showed reddish brown tinged crystals in hematoxylin and eosin stain (A) birefringent under polarized light (B).
first post-RTx month (OR 2.7 per 100 mg additional drug) (p = 0.03) were independently correlated with PTDM.

Conclusion: In this study, we demonstrated that the prevalence of PTDM was relatively high in our cohort reflecting data present in the literature. Interestingly, age at RTx, BMI and cumulative dose of steroids resulted the variables that significantly and strongly influence its development. On the other hand, no relationship was observed between blood values of 25 (OH) D, PTH and the onset of PTDM. Future research, possibly involving a higher number of RTx pts could also evaluate the effects of PTDM on graft and patients on long-term outcome.

COMPARISONS OF CLINICAL OUTCOMES BETWEEN HYPERTENSIVE AND NORMOTENSIVE LIVING KIDNEY DONORS: A NATIONWIDE PROSPECTIVE COHORT STUDY

Jong Ho Kim1, Yu Ho Lee2, Soo-Young Yoon1, Dae Kyu Kim1, So Jin Lim1, Jin Sug Kim1, Kyunghwan Jeong1, Sang Ho Lee1, Ku Yong Chung1, Jong Cheol Jeong1, Soo Jin Na Choi1, Jaeseok Yang2, Myoung Soo Kim1 and Hyeon Seok Hwang2 and Korean Organ Transplantation Registry Study Group 3

1Division of Nephrology, Department of Internal Medicine, College of Medicine, Kyung Hee University Hospital, Kyung Hee University, Seoul, Korea 2Division of Nephrology, Department of Internal Medicine, CHA Bundang Medical Center, CHA University, Seongnam, Korea 3Department of Surgery, Ewha Womans University Mokdong Hospital 4Department of Internal Medicine, Seoul National University Bundang Hospital 5Department of Surgery, Chonnam National University Medical school 6Department of Surgery, Seoul National University Hospital 7Department of Surgery, Severance Hospital, Yonsei University College of Medicine

Background and Aims: Living kidney donors with hypertension is potential candidates to solve the imbalance between supply and demand for renal transplantation. However, the safety of hypertensive donor is not sufficiently ensured after donor nephrectomy and there are limited studies, which compare the clinical outcomes between hypertensive and normotensive donors.

Method: All data from this study were obtained from the Korean Organ Transplantation Registry (KOTRY). A total 672 hypertensive donors and 5,134 normotensive living kidney donors were included from May 2014 to December 2020. Primary outcome was the occurrence of proteinuria and the development of lower renal function, defined as an estimated glomerular filtration rate (eGFR) less than 60 or 45 ml/min/1.73 m².

Results: Compared to normotensive donors, hypertensive donors had lower eGFR before nephrectomy and remained lower after kidney transplantation. However, the risk of eGFR below 60 ml/min/1.73 m² (adjusted HR, 0.87; 95% CI 0.70-1.09; P = 0.226) or below 45 ml/min/1.73 m² (adjusted HR, 1.49; 95% CI 0.77-2.86; P = 0.234) was not significantly increased in hypertensive donors after multiple adjustment. When comparing the rate of eGFR decline between the hypertensive and normotensive donors, there was no significant difference (adjusted unstandardized β = −0.19; −1.15 – 0.76, P = 0.691). The incidence of proteinuria occurrence in hypertensive donor was increased, and it tended to increase even after 4-5 years. Hypertensive donors were found to have significantly more proteinuria than normotensive donors (adjusted HR, 1.83; 95% CI 1.13-2.96; P = 0.014).

Conclusion: Our study indicated that the risk of proteinuria after donation was increased in hypertensive donor, while it was not translated into significant decline in renal function. The continuous and careful monitoring for proteinuria should be required in hypertensive donor after nephrectomy.

#2970
CYTOMEGALOVIRUS INFECTION AND RISK OF NEW-ONSET DIABETES AFTER TRANSPLANTATION: A RETROSPECTIVE STUDY

Muhammad Tassaduq Khan

Dow University Hospital, Renal Transplant Unit, Karachi, Pakistan

Background and Aims: New-onset diabetes after transplantation (NODAT) is one of the common complications reported in patients with kidney transplantation and is associated with risk of infection, poor allograft and patient survival. There is conflicting research literature regarding the role of cytomegalovirus (CMV) infection in increasing the risk of NODAT development.

Method: A total of 59 kidney transplant patients were studied from March 2017 to February 2019. NODAT was defined as two readings of fasting plasma glucose of ≥126 mg/dl at three months post-transplant. CMV viral load was also documented. The 12 months post-transplant allograft and patient survival outcomes were also measured.

Results: Mean age was 43.4 ± 6.2 years. Nearly one-fourth, 14 (23.7%), of the patients had NODAT. CMV viral load and viremia were high in NODAT group; however, the result did not reach statistical significance. CMV DNA replication was statistically high during 1-6 months post-transplant for NODAT group (P<0.001). Only 7 (11.9%) recipients advanced to symptomatic CMV infection. Also, we found that high CMV viremia load was associated with poor kidney allograft function at 12 months.

Conclusion: In summary, this study showed that infection with CMV may not be a risk factor to develop NODAT in patients transplanted with kidney. An elevated CMV viral load may decrease the post-transplant allograft function at 12 months. The prompt diagnosis and timely management of CMV infection could substantially lessen the risk to develop NODAT subsequent worsening of allograft and patient survival.

#2502
THE FREQUENCY AND RISK FACTORS OF NODAT AND ELECTROLYTE DISORDERS IN KIDNEY TRANSPLANT PATIENTS

Elif Başdoğan¹, Servet Başdoğan², Saima Paydas², Bülent Kaya¹ and Yaşar Sertdemir³

¹Çukurova University Faculty of Medicine-Balcalı Hospital, Internal Medicine, Adana, Turkey, ²Nephrology and ³Biostatistics, Adana, Turkey

Background and Aims: The purpose of the study is to investigate at the incidence and risk factors for post-transplant diabetes mellitus (PTDM) in non-diabetic kidney transplant patients (KTRs).

Method: The study included 120 KTRs who did not have diabetes in the pretransplant period. The diagnosis of PTDM was made according to the 2003 ADA DM diagnostic criteria. The relationship between PTDM and clinical and laboratory data on the 0th, 1st, 3rd, 6th, 12th and 24th months was investigated.

Results: The mean age of the patients was 33.3±11.5 years, 65% (78) of them were male. PTDM was developed in 29.1% (35) and 80% of PTDM at first 3 months. The risk factors for PTDM were found to be older (4.4%), family history of diabetes mellitus (5.24 times), beta-blocker use (2.55 times), KTRs with and without PTDM, Pretransplant dialysis type (Hemodialysis (P=0.822) and Peritoneal dialysis (P = 0.583), living donor (101/84.2%)/cadaveric donor (19/15.8%), donor age and gender were similar. Serum magnesium and potassium were different only in the first month between the groups with and without PTDM (P = .019 and 0.008 respectively). The negative effect of PTDM on GFR was not observed in the 2-year follow-up.

Conclusion: It can be predicted that diabetes mellitus may develop with a family history of diabetes, advanced age and the use of beta-blockers. The risk of developing PTDM is higher in the first 3 months and hypomagnesemia in the first month may contribute to diabetes development.
AN OBSERVATIONAL STUDY OF MICRO-VASCULAR COMPLICATIONS OF POST-TRANSPLANT DIABETES MELLITUS IN RENAL TRANSPLANT RECIPIENTS

Anupma Kaul¹, Indrajeet Momin¹, Narayan Prasad² and Dharmendra Bhaduria²

¹Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India and ²Sanjay Gandhi Postgraduate Institute of Medical Sciences, Department of Nephrology, Lucknow, India

Background and Aims: The worldwide incidence of PTDM ranges between 2.5% and 20%. Although there is a good knowledge of PTDM pathogenesis, there is still uncertainty about its proper long-term management. DR, DKD and DSPN are microvascular complications frequently seen in type 1 and 2 DM. Few data are available regarding these complications in patients with PTDM. It remains unclear if the progression of chronic diabetic complications in transplant recipients is similar to that of patients with other types of diabetes. The study was conducted to assess micro-vascular complications in renal transplant recipients with ≥ 5 years duration of PTDM.

Method: This is a retrospective and prospective observational study of PTDM patients conducted between November 2018 to December 2020, at a tertiary care hospital. All renal transplant recipients on follow up at the institute with ≥ 5 years duration of PTDM were included in the study. Patient characteristics and laboratory values were noted from patient files and electronic records. Fundus evaluation was done by direct ophthalmoscopy. If graft kidney biopsy was done for clinical indications, it was included in evaluation. DSPN was assessed through MNSI and 10-g Semmes-Weinstein monofilament examination.

Results: 115 patients with PTDM duration ≥ 5 years were included in the study. Mean PTDM duration was 8.7 ± 3.0 years. None presented findings of diabetic retinopathy at fundus examination by direct ophthalmoscopy. 37.4% patients had DSPN which was associated with PTDM duration (p value < 0.03, 95% CI, 0.93 to 0.99). The mean eGFR was 59.2 ± 21.8 ml/min/1.73 m², 53.9% patients had eGFR ≥ 60 ml/min/1.73 m². 35.7% patients had proteinuria ≤ 300 mg/day. 23 (20%) patients with PTDM duration ≥ 5 years underwent graft kidney biopsy, 4 biopsies were reported as de-novo DKD, 6 biopsies were reported as suggestive of DKD. The patients with DKD had mean PTDM duration of 143.3 ± 52.4 months, mean eGFR 44.8 ± 21.8 of and a median proteinuria of 2653 mg (IQR 2758). In secondary analysis of the 23 biopsied patients PTDM duration was associated with DKD development (p value = 0.196; 4.2 ± 4.9 vs. 5.1 ± 2.9 months, p = 0.231 respectively). In multivariate logistic analysis, there was no significant difference regarding the total exposure to CNI and follow-up duration (sensitization group: multivariate odds ratio [OR] 1.188, 95% confidence interval [CI] 0.55–2.52, p = 0.655, OR 1.03, 95% CI 0.97–1.10, p = 0.282, respectively). In some patients, even prolonged immunosuppression

Conclusion: The initiation of microvascular complications does not seem to be as accelerated as previously supposed. DR may not be as strongly associated with de-novo DKD in PTDM patients as seen in type 1 and type 2 diabetes mellitus. PTDM seems to be a unique type of diabetes, and its consequences may be milder than expected in type 1 and type 2 diabetes.

IMMUNOSUPPRESSION FOR FAILED ALLOGRAFT: HOW PROlongED AND MUCH IS ADEQUATE?

Jehun Song, Kyungsun Park, Kyung Don Yoo, Jongha Park and Jong Soo Lee

Ulsan University Hospital, Division of nephrology, Department of Internal Medicine, Ulsan, Rep. of South Korea

Background and Aims: The development of human leukocyte antigen (HLA) antibodies towards a failed allograft is a critical factor for the feasibility and outcomes of future transplantation. Therefore, we investigated the factors contributing to sensitization in patients with failed allografts.

Method: A single-center retrospective study of patients with failed allografts between 2010 and 2020 was performed. Samples for HLA antibodies were tested at the time of graft failure and after immunosuppression withdrawal. Sensitization was defined as more than 80% of calculated Korean panel reactive antibody (PRA) I or PRA II. In addition, variables for affecting sensitization were collected.

Results: Twenty-three patients were included in the study. The mean flow-up duration after failed allograft was 43 ± 33.3 months. The sensitized patients tended to have a longer flow-up period and were exposed to less total calcineurin inhibitor (CNI) than non-sensitized patients. (non-sensitized vs sensitized patients: 27.1 ± 12.9 vs 51.7 ± 37.8 months, p = 0.196; 4.2 ± 4.9 vs. 5.1 ± 2.9 months, p = 0.231 respectively). In multivariate logistic analysis, there was no significant difference regarding the total exposure to CNI and follow-up duration (sensitization group: multivariate odds ratio [OR] 1.188, 95% confidence interval [CI] 0.55–2.52, p = 0.655, OR 1.03, 95% CI 0.97–1.10, p = 0.282, respectively). In some patients, even prolonged immunosuppression
after returning dialysis therapy did not prevent sensitization toward failed allografts.

**Conclusion:** In this study, there was no significant difference regarding the contributing factors for sensitization in the multivariate logistic analysis. However, in sensitized patients, trends were showing longer follow-up duration and less CNI exposure. Sensitization towards a failed graft might be affected by the dose and duration of immunosuppressant. Finally, the small sample size is one of the limitations of this study, and additional prospective research analysis for patients with failed allografts is needed in the future.

## #5095

**THE CURIOUS CASE OF GAS IN THE GRAFT KIDNEY**

**Rachana Shenoy and Narayan Prasad**

Sanjay Gandhi Post Graduate Institute of Medical Sciences, Nephrology, Lucknow, India

**Background and Aims:** Emphysematous pyelonephritis (EPN) denotes a severe infection of renal parenchyma resulting in necrosis and gas accumulation in the renal and perirenal tissue. Risk factors for urinary tract infections in renal transplant recipients include advanced age, female gender, reflux nephropathy prior to transplantation, diabetes mellitus, deceased donor kidney, kidney–pancreas transplant, retransplantation, antibody induction for immunosuppression, urinary bladder catheterisation, history of allograft rejection with subsequent escalation of immunosuppressive therapy, and use of ureteral stents. There are no definite guidelines for management of EPN in renal allografts. If unstable and deteriorating, graft nephrectomy should be undertaken as soon as possible. Any delay in surgical intervention, be it percutaneous drainage or nephrectomy may result in death.

**Method:** A 25-year old male, diagnosed with IgA Nephropathy (IgAN) received a living donor renal transplant from his mother in 2013 after a diuresis vintage of 3 years. He received Basiliximab induction followed by maintenance immunosuppression with Tacrolimus, Mycophenolate mofetil and Prednisolone. He had no history of UTI in the immediate post-transplant period. His blood glucose levels were within normal limits and he had not had any urological intervention. In 2019, patient was diagnosed with IgAN recurrence as a cause of chronic renal allograft injury. His Creatinine at last follow up in July 2022 was 4.1 mg/dl. He presented in September 2022 with fever, chills, vomiting, pain in the right iliac fossa and inability to extend his right leg. At presentation, his BP was 86/60mmHg, with pyrexia and tachycardia. Ultrasonography revealed an ill-defined collection superomedial to the graft kidney with doubtful posterior extension and air foci. Non-contrast CT study revealed a large subcapsular collection, extending posteriorly into the right iliac fossa involving the right psoas major and inferiorly into the pelvis, with air foci and no evidence of any urinary tract obstruction suggestive of Acute Emphysematous pyelonephritis with ruptured abscess. He was started on broad-spectrum iv antibiotics- Meropenem and Levofloxacin. Immunosuppression was reduced. Laboratory investigations revealed total leucocyte count of 37,000 cells/mm³, Creatinine of 11 mg/dl, urine routine microscopy revealed field full of pus cells. Blood and urine cultures grew ESB1 Escherichia coli. He was taken up for urgent urological intervention in the form of percutaneous drain insertion. Frank pus was aspirated and 200ml drained instantaneously, cultures of which demonstrated the same organism. Within 24 hours of pus drainage, patient became afebrile and had pain relief. He was given 3 weeks of culture-propriate iv antibiotics, to continue another 3 weeks of oral Carbapenem. However, his graft dysfunction persisted, with no recovery and he became dialysis-dependent.

**Discussion:** EPN of the renal allograft is a rare occurrence. A study of EPN in renal transplant recipients by Alexander et al from 2012 revealed 18 out of 22 patients were diabetics, 9 necessitated graft nephrectomy and 7 required percutaneous drainage in addition to antibiotics. Till date, up to 30 cases of graft EPN have been reported in English literature. The striking feature is that more than 90% of these cases were diabetic.

**Conclusion:** The complete pathogenesis of renal allograft EPN, especially in patients with no apparent traditionally described risk factors remains yet to be understood. A high degree of suspicion and early intervention may help to save the allograft.

## #5691

**BK POLYOMAVIRUS VIREMIA AND VIRURIA ARE ASSOCIATED WITH SEVERE INFLAMMATION AND FIBROSIS IN RENAL ALLOGRAFTS, BUT NOT WITH GRAFT SURVIVAL**

**Gonçalo Ávila1, Rita Manso2, Patricia Matias3 and André Weigert1**

1Hospital Santa Cruz, Nephrology and Renal Transplantation Unit, Carnaxide, Portugal and 2Hospital Santa Cruz, Pathology Department, Carnaxide, Portugal

**Background and Aims:** Infection of the renal allograft by Polyomavirus BK (BKV) can cause acute tubular cell injury and interstitial inflammation, which leads to subsequent interstitial fibrosis and tubular atrophy (iIFTA). The presence and degree of inflammation within these areas (i-IFTA) is associated with worse outcomes in kidney transplant (KT) patients. The aim of this study was to investigate the association between BKV viremia and viruria and the presence of iIFTA and i-IFTA, decline of renal function, and graft loss.

**Method:** We conducted a single-center retrospective case-control study, which included all patients who underwent an allograft biopsy between January 2018 and December 2022. All biopsies were made for cause (allograft dysfunction with increased serum creatinine). Real-time polymerase chain reaction was used to detect and quantify BK viral load in serum and urine samples. Patients were included if they had at least 6 months since KT and if they had serial evaluation of BKV viremia and viruria previously to the biopsy. We calculated, in the graft biopsy, the percentage of iIFTA, and also i-IFTA. Estimated glomerular filtration rate (eGFR) was obtained at baseline and 1 year after the biopsy. Graft loss was evaluated at 6 months and 1 year after the biopsy. **Results:** Mean age of the population was 53.5 years and 67% were males. A total of 116 biopsies were performed during the studied period and 72 met the inclusion criteria. Ten percent of patients developed persistent (≥ 3 months) BKV viremia, 24% developed persistent BKV viruria, and 18% developed persistent JCV viruria. Five cases of polyomaviruses-associated nephropathy were diagnosed. The other most common diagnoses were T cell-mediated rejection (24%), antibody-mediated rejection (15%), and focal segmental glomerulosclerosis (15%). In patients with persistent BKV viremia, a higher viral load had a strong positive association with the degree of i-IFTA (r=0.954; \( P = 0.001 \)). Patients with BKV viremia and/or viruria were more likely to present more severe iIFTA (≥ 40%) and i-IFTA (grade ≥ 2) in allograft biopsy (\( P = 0.03 \)). Patients with higher degrees of iIFTA and i-IFTA were more likely to experience graft loss 1 year after the biopsy (\( P = 0.01 \)). There was no significant association between the presence of BKV viremia and/or viruria and the decline of eGFR, nor with the incidence of graft loss 1 year after the biopsy. In multivariable analysis adjusted for age, eGFR at the time of biopsy; the presence of donor-specific antibodies and the main diagnosis of allograft biopsy, the presence of BK viremia and/or viruria was a significant predictor of more severe iIFTA and i-IFTA (\( P = 0.04 \)).

**Conclusion:** In our population, higher BK viremia loads were associated with more extensive inflammation within areas of iIFTA. Patients with BK viremia and/or viruria, independently of the main diagnosis of the biopsy, were more likely to exhibit more severe iIFTA and i-IFTA in allograft biopsies, but no association with the incidence of dialysis at 1 year was shown. Longer prospective studies are needed to investigate whether BKV infection treatment/ reduction of immunosuppression can slow down fibrosis progression and minimizes i-IFTA.
for regular monitoring were collected from patients before RT, every 2 weeks first 3 months, then at 6, 9, 12 months after RT. In the case of complication development samples from patients were collected later then 1-year monitoring period. PyV DNA was detected by real-time PCR. Viral DNAs from 17 BKV-positive and 11 JCV-positive patients were molecular typed by partial sequencing of VP1 genome region. Confidence intervals for the proportions were calculated using Wald’s method.

Results: Results showed that PyV detection total frequency in the group 1 was 14.47% [11.32%; 18.3%], almost all patients developed viruria, only 2.54% [1.32%; 4.67%] had viremia. In the group 2 PyV DNA was detected in 46.07% [40.96%; 51.26%] of recipients: 19.10% [15.34%; 23.52%] had BKV infection, 19.94% [16.11%; 24.42%] – JCV, 7.02% [4.76%; 10.2%] – BKV+JCV mixed infection. Frequency of viremia was 6.74% [4.53%; 9.87%] in this group. Maximal BKV viral load levels reached 1.2 × 10^{12} copies/ml in urine and 5.9 × 10^7 copies/ml in serum. JCV loads were up to 3 × 10^9 copies/ml in urine and 1.2 × 10^8 copies/ml in serum. Then we analyzed frequency of PyV detection before RT and during the first year after RT among the 102 recipients. Results displayed on the fig.1 showed that the peak of PyV infection registration was 30 days after RT. Quantitative monitoring of viral load in posttransplant period was the basis for the correction of the applied immunosuppressive therapy regimens in relation to the recipients with a high viral load (higher than 1 × 10^10 copies/ml in urine or 1 × 10^8 copies/ml in serum). The results of molecular typing showed that 17 BKV isolates belonged to subgroups Ib-2 and IcV-2 (12 and 5 isolates, respectively). Within subgroups Ib-2 isolates formed 3 clusters corresponding 3 separate genovariants. JCV isolates belonged to subtype 1A, 1B and 2A (7, 17 BKV isolates belonged to subgroups Ib-2 and IcV-2, 12 and 5 isolates, respectively). The last one had 99% nucleotide sequence similarity with Greece and South Korea isolates.

Conclusion: Our data demonstrated an importance of PyV DNA monitoring of kidney recipients in the posttransplant period starting from the first days after RT to predict development of PyV complications as PyVAN, HC or others by correcting the immunosuppressive therapy.

HYPERTENSION & DIABETES

ESTRADIOL REPLACEMENT MITIGATED BLOOD PRESSURE ELEVATION VIA SUPPRESSION OF NCC IN ANGIOTENSIN II-INFUSED OVARIECTOMIZED FEMALE RATS

Yang-Gyun Kim1, Sang-Ho Lee1, Ju-Young Moon1, Su Woong Jung1, Jihoon Park1, In Tae Jin1, Yoosoon Joo1 and Minhue Cho2

1Kyung Hee University Hospital at Gangdong, Nephrology, Seoul, Rep. of South Korea and 2University of Memphis, School of social work, Memphis, United States of America

Background and Aims: Female rats excrete more urine sodium than male rats with similar blood pressure (BP). However, it is not clear whether the sex difference in pressure natriuresis is conserved in menopausal rats. We assessed whether the natriuretic response and renal sodium transporter activity in ovariectomized female rats infused with angiotensin II (ANGII) could be affected by estrogen supplementation.

Method: Six-week-old female Sprague-Dawley rats (n = 30) were ovariectomized (OVX, n = 20) or sham-operated (n = 10) (−4 weeks, −4W). After 2 weeks, subcutaneous estradiol was administered to half of the OVX rats (n = 10) for 4 weeks (−2W~−2W).

Results: ANGII-infused VP1 genome region. Confidence intervals for the proportions were calculated using Wald’s method.

Results: ANGII-induced BP elevation was highest in the OA group, followed by the FA and OEA groups. Urine sodium tended to increase after ANGII infusion in OA and OEA but decreased in OA. Western blot results showed that cortical phosphorylated sodium chloride cotransporter (pNCC) tended to be augmented by ANGII treatment in FA and OA, but mitigated in OEA. Cortical ANGII type 2 receptor (AT2R) expression was significantly higher in estradiol-treated OVX rats than in OVX rats, irrespective of ANGII infusion. Similarly, the enhanced pNCC in ANGII-treated distal convoluted tubular cells was reversed by estradiol treatment. In KoGES data, urine sodium was significantly lower in postmenopausal women than in premenopausal women, despite the higher BP.

Conclusion: Estradiol reversed BP elevation and augmented the natriuretic response in ANGII-infused OVX rats and distal tubular cells via suppression of pNCC and increase of AT2R.

AN ANTI-FIBROTIC GENE ATTENUATES DIABETIC KIDNEY INJURY IN DB/DB MICE BY INHIBITING FIBROSIS VIA EPITHELIAL-MESENCHYMAL TRANSITION PATHWAY

Seunghye Lee1, Jin Hyun Kim1,3, Hyun Seop Cho4, Ha Nee Jang1, Sehyun Jung2, Jung Hwa Jung1,3, Se-Ho Chang1,3,5, Hyun-Jung Kim1,3

1Gyeongsang National University Hospital, Internal Medicine, Jinju, Rep. of South Korea, 2Gyeongsang National University Hospital, Biomedical Research Institute, Jinju, Rep. of South Korea, 3Gyeongsang National University, Institute of Health Sciences, Jinju, Rep. of South Korea, 4Good Morning Internal Medicine Clinic, Daegu, Rep. of South Korea and 5Gyeongsang National University, College of Medicine, Internal Medicine, Jinju, Rep. of South Korea

Background and Aims: Diabetic nephropathy (DN) is a major cause of mortality in patients with diabetes and chronic kidney disease, but there is a lack of effective therapeutic drugs for this disease. The development and progression of DN is influenced by fibrosis. Transforming growth factor (TGF)-β1 is a key cytokine involved in fibrosis in many different organ systems. Anti-fibrotic gene (Anti-F) is a TGF-β/Smad signaling. Here we examined the therapeutic effect of Anti-F in a model of DN using db/db mice with streptozotocin (STZ) treatment.

Method: The db/db mice were divided into five groups; db/db + (wild type), db/db + saline, db/db + STZ, db/db + STZ + CMV-Anti-F, and db/db + STZ + TGF-β - Anti-F. STZ was peritoneally injected for five consecutive days (50mg/kg) and Anti-F (40μg/head) was peritoneally administered once every two weeks. Mice were sacrificed four months after STZ injection.

Results: The Anti-F with CMV and TGF-β promoter administration markedly alleviated metabolic syndrome assessed by obesity and hyperglycemia, and renal dysfunction assessed by renal overweight and albuminuria in db/db + STZ mice. The administration obviously mitigated glomerular damage in diabetic mice, as reflected by the reduced increase mesangial expansion and the expression of nephrin and podocin in db/db + STZ mice. Additionally, renal interstitial fibrosis was also significantly inhibited by Anti-F through suppressing epithelial-mesenchymal transition (EMT) signaling including α-
SMA, Twist, and Snail, as well as inflammation reflected by IL-1β, MMP-2, and MMP-9 in diabetic rats.

**Conclusion:** Anti-F attenuated the development of DN in db/db mice with type 2 diabetes. The protective effect was associated with decreased inflammation and subsequent attenuation of EMT-mediated renal fibrosis. Thus, this study suggests that targeting the Anti-F could be considered as a novel therapeutic approach for preventing the progression of DN.

#4419

**THE IMPACT OF TRANSGlutaminase 2 INHIBITION ON HYPERTENSION-INDUCED FIBROSIS IN HYPERTENSIVE NEPHROPATHY**

Jiwon Lee, Sang-Woong Han, Seung Hee Yang and Mi-Yeon Yu

Rep. of South Korea

**Background and Aims:** Hypertensive nephropathy is a chronic disease that requires the novel treatment. Transglutaminase 2 (TG2), linked to various diseases including cardiovascular and kidney diseases, has been suggested to play a role in the development of hypertensive nephropathy through its contribution to fibrous tissue formation, oxidative stress regulation, and inflammation. This study aimed to explore the role of TG2 in the development of hypertensive nephropathy and evaluate its potential as a therapeutic target.

**Method:** An in vitro hypertensive model was established using a device that mimics hypertension by applying rotational force. An in vivo hypertensive model was established in rats through subtotal 5/6 nephrectomy to induce fibrosis. The relationship between TG2 expression and the progression of hypertension-induced fibrosis was analyzed, and the impact of TG2 inhibition on fibrosis was evaluated using the TG2 inhibitor, cysteamine.

**Results:** In the in vitro study, rotational force was applied to induce hypertension using a hypertensive mimic device, which resulted in fibrosis in primary human glomerular endothelial cells and tubular epithelial cells and increased expression of TG2. The administration of cysteamine at concentrations of 0.5 mM, 1 mM, and 2 mM decreased fibrosis and phosphorylated P65 in a dose-dependent manner. The in vivo hypertensive model demonstrated a significant increase in blood pressure (P < 0.001) and kidney fibrosis (P < 0.001) over time at 4 and 8 weeks after surgery. A significant increase in TG2 expression was observed as hypertension and fibrosis progressed (P < 0.001).

**Conclusion:** The progression of hypertension-induced fibrosis was accompanied by an increase in TG2 expression. Inhibition of TG2 showed improvement in fibrosis, suggesting further study of its mechanism may provide new therapeutic options for hypertensive nephropathy.

#4945

**NEPHROPROTECTIVE EFFECTS OF Dipeptidyl peptidase–IV INHIBITORS FROM PHENOLIC RICH FRACTION OF TRIGONELLA FOENUM IN DIABETIC NEPHROPATHY RATS**

Anand Krishna Singh and Purnima Tripathi

Shri Vaishnav Vidyapeeth Vishwavidyalaya, Life science, Indore, India

**Background and Aims:** The most common effect of renal disease in the world is diabetic nephropathy (DN). Dipeptidyl peptidase-IV (DPP-IV) enzyme is most abundant present in kidney, which is increased in diabetic nephropathy. A novel approach to treat type 2 diabetes mellitus (T2DM) along with DN, based on incretin hormones: glucagon-like peptide-1 (GLP-1) which regulated by DPP-IV. We hypothesized that DPP-IV inhibitors isolated from phenolic rich fraction of Trigonella foenum (TF) will regulate DPP-IV activity as well as DN: *in vivo; in-silico* and kidney histology.

**Method:** DPP-IV inhibitors from phenolic rich fraction of TF in high sucrose diet along with dexamethasone induced T2DM was explored *in-vivo* in rat. Apart from serum glucose, DPP-IV, and inhibition activity, HbA1c, Insulin was estimated. We also examined GLP-1, albuminuria, and antioxidant properties in kidney tissue along with histology. Molecular docking of phenolic rich fraction (Gallic acid) of TF with DPP-IV.

**Results:** High sucrose diet with Dexamethasone administration (1 mg /kg BW 45 days) increased concentration of serum glucose, DPP-IV and albuminuria, cholesterol and renal LPO with increase in tissue antioxidant to scavenging free radicals generated by oxidative stress, but after some time antioxidants such as SOD, CAT, GSH was decreased. However, after administration of phenolic rich fraction of TF, DPP-IV inhibition activity increase in TF (71.1%), as compared to Sitagliptin (89.5%) with significant reduction in levels of glucose, albuminuria, TC, TG and with increased Insulin and GLP-1. Kidney histology showed some significant change as compared to diabetes control. Isolated Gallic acid depicts the conformer and affinity energy was – 5.3 and distance from RMSD 1b was 38.669. Sitagliptin depicted the conformer and affinity energy was – 8.9 and distance from RMSD 1b was 3.826.

**Conclusion:** DPP-IV inhibitors isolated from TF are nephroprotective, with novel antioxidant properties. DPP-IV inhibition lower blood glucose by decreasing DPP-IV activity, albuminuria and increasing levels of GLP-1.

#5018

**EFFECTS OF CANDESARTAN COMPARED TO LOSARTAN ON INHIBITING MESANGIAL EXPANSION IN DIABETIC MODEL RATS RECEIVING ROSMARINIC ACID**

Pandu Tridana Sakti1, Nur Samsu2 and Achmad Rifai2

1Faculty of Medicine Brawijaya University, Internal Medicine, Malang, Indonesia and 2Faculty of Medicine Brawijaya University, Nephrology, Malang, Indonesia

**Background and Aims:** Oxidative stress and activation of the renin-angiotensin system (RAS) due to chronic hyperglycemia are the pathogenesis of diabetic nephropathy (DN). Until now, therapy for DN has not shown satisfactory results. Rosmarinic acid (RA) which has antioxidant, anti-inflammatory, anti-fibrosis effects, and ARB which can inhibit RAS activation may have a synergistic effect to prevent DN progression. This study aims to determine the effect of inhibiting mesangial expansion in diabetic rat models after being given a combination of RA and ARB (candesartan or losartan).

**Method:** True experimental laboratory trial with randomized post-test only control group method on Rattus norvegicus strain Wistar rats. Diabetic rats were prepared by giving a high-fat diet (60% fat calories) and a single injection of 40 mg/kg streptozotocin. Mice were divided into 4 groups, each consisting of 4 rats: negative control (healthy rats); positive control (placebo diabetic rats); diabetic rats that received RA and candesartan; diabetic rats that received RA and losartan. The rat glomerulus was evaluated to assess mesangial expansion using ImageJ 1.48 software after 8 weeks of treatment by a pathologist blindly. Data analysis with One-way ANOVA and Tukey’s post hoc tests.

**Results:** The results of the percentage of the mesangial matrix in the positive control group (81.49% ± 1.45) were higher than the negative control group (58.82% ± 0.99). The results of the percentage of the mesangial matrix in the RA + candesartan treatment group (61.56% ± 0.35) and the RA + losartan treatment group (62.28% ± 0.77) showed lower results than the positive control group, with the One-way ANOVA test results showing significant differences (p < 0.000). Tukey’s post hoc tests showed the positive control group that received a high-fat diet and induced diabetes with STZ significantly increased mesangial expansion compared to negative control (MD: [22.66]; 95% CI: [20.62], [24.72]; p: 0.000). The RA + candesartan treatment group significantly inhibited mesangial expansion compared to the positive control (MD: [19.92]; 95% CI: [-21.97], [-17.87]; p: 0.000), as well as the RA + losartan treatment group (MD: [19.21]; 95% CI: [-21.26], [-17.16]; p: 0.000). The RA + candesartan treatment group showed a better effect in inhibiting mesangial expansion compared to the RA + losartan treatment group, but not significantly (p: 0.735).

**Conclusion:** The combination of rosmarinic acid with candesartan or losartan has the effect of inhibiting mesangial expansion in diabetic rats.
INVESTIGATING TREM2 MACROPHAGES IN CHRONIC KIDNEY DISEASE

Giorgio Trivioli¹, Nathan Richoz², Ayshwarya Subramanian³, Katherine Vernon³, Patrick Trotter³, Yiming Zhou³, Jillian Shaw³, Anna Greka³ and Menna Clatworthy²

¹Cambridge University Hospitals, Nephrology, Cambridge, United Kingdom, ²University of Cambridge, Medicine, Cambridge, United Kingdom, ³Broad Institute of MIT and Harvard, Cambridge, United States of America and ⁴Sun Yat-sen University, P.R. China

Background and Aims: Kidney macrophages have been implicated in interstitial fibrosis and inflammation in various forms of chronic kidney disease (CKD), but subsets with different markers and putative functions have been identified through the application of single cell technologies. A recent study from the Greka Lab revealed distinct macrophage populations in the human kidney bearing lymphatic endothelium hyaluronic receptor-1 (LYVE1) and triggering receptor expressed on myeloid cells-2 (TREM2). Notably, TREM2⁺ macrophages, which have been implicated in limiting metabolic toxicity in chronic diseases, were enriched in diabetic mouse kidneys and human kidneys from obese individuals (Subramanian et al. BioRxiv 2021). To support these findings, we aimed at characterizing LYVE1⁺ and TREM2⁺ macrophages in kidney samples taken from subjects with CKD-associated co-morbidities, including hypertension, diabetes mellitus and obesity.

Method: We performed immunofluorescence microscopy of samples collected from the cortex of kidneys donated for transplantation but deemed unsuitable for implantation. Each sample was stained with anti-CD163, -LYVE1, and -
TREM2 antibodies, plus Hoechst to stain nuclei. Two identically sized fields of view were imaged in each sample. Macrophages were identified based on CD163 expression and the expression of the LYVE1 and TREM2 in macrophages delineated. Macrophage subsets were compared according to age, BMI, eGFR and the presence of hypertension, obesity and diabetes.

**Results:** of 49 donors assessed, 19 (39%) were “healthy”, six (12%) “hypertensive” without obesity or diabetes, 16 (33%) “obese” with no evidence of diabetes, and 8 (16%) “diabetic” (all had type 2 diabetes and 6/8 were also obese) The median eGFR at donation was 95 mL/min/1.73 m² and none of the donors had a history of CKD. Gender, median age and cause of death were not significantly different as well (Table 1). “Healthy”, “hypertensive” and “obese” donors had similar numbers of total macrophages, LYVE1+ and TREM2+ macrophages per region of interest. In contrast, “diabetic” subjects had a tendency towards a higher macrophage count ($P = .10$) and significantly higher numbers of LYVE1+ ($P = .02$) and TREM2+ macrophages ($P = .002$), compared to “healthy” ones (see Figure 1). The median LYVE1+/CD163+ ratio was 0.69 and did not differ substantially between the groups ($P = .18$), while the TREM2+/CD163+ ratio was higher among “diabetic” compared to “healthy” donors ($0.43$ vs $0.34$, $P = .06$).

**Conclusion:** Diabetes is associated with an increase in kidney macrophages, particularly in those expressing TREM2. Further investigation is required to determine the role these cells may play in CKD progression.

**BMI, body mass index; eGFR, estimated glomerular filtration rate; IQR, interquartile range; HTN, hypertensive**

Figure 1:
**Background and Aims:** Diabetic mellitus (DM) is the most common cause of chronic kidney disease (CKD) [1]. The prevalence of CKD is therefore increasing worldwide with increasing prevalence of DM [1]. Among those with DM, CKD prevalence varies widely between countries. The actual prevalence of CKD in patients with DM in Turkey is unknown. This study aimed to determine frequency of CKD among diabetic patients of Cappadocia cohort and patients’ awareness about the disease.

**Method:** A total of 1591 diabetic patients from the Cappadocia cohort were invited to this cross-sectional study. A trained study team administered a questionnaire for patients’ medical history, knowledge, attitudes, and awareness of the disease and measured patients’ blood pressures (BPs) at least three times using an automated device. Serum creatinine was measured and spot urine albumin/creatinine ratio (ACR) measurements were performed for three consecutive days. A diagnosis of CKD was established if glomerular filtration rate (GFR) is < 60 mL/min or ACR is > 30 mg/g.

**Results:** The mean age of the patients was 63±10 years. Overall, 60.9% patients were obese (body mass index ≥ 30 kg/m²), and 70% patients were hypertensive. HbA1c was analyzed in 98.2% of the patients; HbA1c was <7% in 27.4%, ≥7%–<8% in 20.8%, >8%–<9% in 17.7%, and >9% in 34.1% of the patients. 1535 patients with blood and urine analyses, 231 of 1008 (22.9%) females and 154 of 527 (29.2%) males had CKD (P = .007). Among patients with GFR values, 11.4% had a GFR of <60 mL/min and 88.6% had a GFR of ≥60 mL/min. Among 1544 patients with ACR measurements, 18.2% had values ≥30 mg/g and 4.4% had values ≥300 mg/g. CKD was detected in 385 (25.1%) of 1535 patients with both GFR and ACR values (Figure 1). Of these patients, 28.1% had Stage 1, 25.7% had Stage 2, 32.5% had Stage 3A, 11.2% had Stage 3B and 2.6% had Stage 4 or 5 CKD. Excluding two patients with missing data, 36 of 383 CKD patients (9.4%) knew that they had CKD. In the logistic regression analysis, old age (OR = 1.05, 95% CI 1.03-1.07; P < 0.001), male sex (OR = 2.11, 95% CI 1.43-3.12; p < 0.001), duration of DM (OR = 1.03, 95% CI 1.00-1.05; P = .022), morbid obesity (OR = 3.58, 95% CI 1.28-10.03, P = .015), a CRP level of >5 mg/L (OR = 1.60, 95% CI 1.12-2.27; P = .009), a triglyceride level of ≥150 mg/L (OR = 1.74, 95% CI 1.24-2.45; P = .002), and grade 3 hypertension (OR = 2.13, 95% CI 1.02-4.44; P = .043) were found to be significantly associated with an increased risk of CKD in patients with DM.

**Conclusion:** In the present study, CKD prevalence among diabetic patients in Turkey was 25.1%. Overall, 53.8% of the patients with CKD had a GFR of ≥60 mL/min although they had an ACR of ≥30 mg/dL; that is, if albuminuria was not studied, this subgroup of patients would have been considered to have normal kidney function according to GFR. The awareness of CKD was found to be quite low in the patients. Therefore, periodic screening of diabetic patients should always include urinalysis, particularly ACR, as well as serum creatinine, fasting blood glucose and HbA1c.

**Reference**
A common clinical finding in patients with type 2 diabetes mellitus is hypertension. A recent study conducted at the Nephrology department of a tertiary healthcare center in Italy aimed to determine the prevalence and etiology of biopsy-proven non-diabetic renal disease (NDRD) and to explore the clinical differences encountered in the diabetic patient with NDRD.

**Background and Aims:** The study was conducted at a university hospital, which served as a tertiary healthcare center. One hundred and three diabetic patients underwent a renal biopsy due to suspicion of NDRD from January 2012 to December 2022 at Nephrology department. Collected data comprised demographic information, indication and result of renal biopsy, lab results (serum creatinine, HbA1c, proteinuria, albuminemia, hematuria, presence of active urinary sediment and presence of auto antibodies) and disease's characteristics (duration of diabetes, presence of diabetic retinopathy).

**Method:** A retrospective study of the medical records of all diabetic patients who underwent a renal biopsy due to suspicion of NDRD from January 2012 to December 2022 at Nephrology department. Collected data comprised demographic information, indication and result of renal biopsy, lab results (serum creatinine, HbA1c, proteinuria, albuminemia, hematuria, presence of active urinary sediment and presence of auto antibodies) and disease's characteristics (duration of diabetes, presence of diabetic retinopathy).

**Categorical variables are presented as frequencies and percentages, continuous variables as means and standard deviations, or medians and interquartile ranges (IQR) for variables with skewed distributions. A p-value < 0.05 was considered statistically significant.** Statistical analysis was performed using SPSS version 28.1 for MacOS X. The most frequent indication for renal biopsy was chronic kidney disease (CKD) (26.3%), followed by rapidly progressive renal failure and nephrotic syndrome (26.3%). In our population, 22.9% had DN and 77.1% had NDRD. Pauciimmune Glomerulonephritis (14%) and Membranous Nephropathy (10.5%) were the most common causes of NDRD. A chi-square test was performed to examine the relation between the two groups (ND vs NDRD) and the presence of diabetic retinopathy. There was a statistically significant association between the two variables (χ²=7.778, p=0.01). Mann-Whitney test was performed to compare the median of the duration of the diabetes and HbA1c in two groups. That showed a statistically significant difference (U = 357, P = 0.018 and U=335.5, P = 0.013 respectively).

**Conclusion:** Since renal biopsy is critical to establish the correct diagnosis and provide an appropriate treatment, it should be performed in patients with high suspicion of NDRD, especially in patients with a recent diagnosis of diabetes, good metabolic control and the absence of diabetic retinopathy.

**Method:** The study was conducted at a university hospital, which served as a tertiary healthcare center. One hundred and three diabetic patients who underwent a renal biopsy due to suspicion of NDRD were involved in the study. Demographic characteristics, physical examination findings, laboratory tests and kidney biopsy findings were retrospectively evaluated.

**Results:** According to kidney biopsy findings 30 patients (29.1%) had isolated diabetic nephropathy. NDKDs were present in 73 (70.9%) of the patients. 78.1% of the patients with NDKDs had non-diabetic glomerular diseases. Among glomerular diseases, focal segmental glomerulosclerosis (36.9%), IgA nephropathy (17.8%) and membranous nephropathy (13.7%) were the leading three diseases. The duration of diabetes (p=0.00), HBA1C level (p=0.00) and the amount of proteinuria (p=0.02) were higher in patients who had isolated diabetic nephropathy. Presence of diabetic retinopathy (p=0.00), concomitant vascular diseases (p=0.02) and the use of insulin treatment were also more often in patients with isolated diabetic nephropathy. Multivariate analysis revealed that patients with higher HBA1C levels and longer diabetes duration had more tendencies to have isolated diabetic nephropathy. Immunosuppressive treatments for glomerular diseases were administered in around 50% of the patients. However, renal and overall survivals were not different between patients who received immunosuppressive treatments and those who didn’t.

**Conclusion:** A renal biopsy in diabetic patients might be preserved for those with shorter diabetes duration and lower HBA1C levels. As poor glycomic control and susceptibility to infections pose additional risks, immunosuppressive treatments might not always be beneficial.

**Method:** A retrospective, cross-sectional study at the Department of Nephrology at Mongi SL Hospital, and we studied the relation between blood pressure levels and CKD stages. The stage of chronic kidney disease (CKD) was defined according to the KDIGO 2012 classification.

**Results:** A total of 99 patients were enrolled in this study. The mean age was 69.19 years (range 30-96) with a gender ratio M/F of 1.225. The patients who had hypertension were 41 (46.06%). We noted the presence of chronic kidney disease stage 3 or more in 64 patients (71.91%) among whom 32 patients had hypertension. Thirty-seven patients had a stage 3 CKD, 14 had a stage 4, and 13 had a stage 5. As for blood pressure levels, the mean systolic blood pressure was 137.94 mmHg, and the diastolic 79.52 mmHg. Twenty-three patients had stage 1 hypertension and 13 presented a stage 2 hypertension. Stage 3 hypertension was noted in 5 patients, who all had a stage 3 or 4 chronic kidney disease. Higher blood pressure levels were noted in patients with CKD stage 3 or more: Among the 13 patients who had a stage 5 chronic kidney disease, 7 had hypertension.

**Conclusion:** Hypertension is ubiquitous in the chronic kidney disease, and it can be a cause or consequence of CKD. Both hypertension and CKD contribute to each other and it has been noted that patients with CKD are at higher risk for hypertension-related adverse outcomes, including cardiovascular disease, and therefore, the management of hypertension is particularly important in patients with CKD.
evaluate the genetic aspects of pathways related to hypertension and renal failure, and to Na-k-pump activity such as endogenous ouabain and RAAS system, in order to partly dissect the wide clinical spectrum of the disease in hospitalized patients infected by SARS-CoV-2, with various degrees of symptoms.

**Method:** We investigated the relationship between three outcomes and genetic determinants in the COVID-BioB study (ClinicalTrials.gov NCT04318366), a characterization of an Italian cohort of about 500 patients, a SARS-CoV-2 positive population recruited during the first wave of pandemic at San Raffaele Scientific Institute with biological samples and clinical assessment data available in an internal biobank. Targeted DNA genotyping was performed by custom arrays on TaqMan OpenArray system (ThermoFisher) for single nucleotide polymorphisms (SNPs). The genetic variants were selected as candidates for salt-sensitive hypertension and renal failure. Associations with genetic markers and outcomes were carried out with logistic regression analysis for outcome absence/presence comparison.

**Results:** COVID-19 patients were all hospitalized, with mean age 67.4±13.5 (30.2% female), pneumonia 96.9%, hypertension 51.8%, coronary arterial disease 26.8%, emergency department AKI stage 1-11.1%, AKI stage 2-0.4%, CKD stage>311.5%, Chronic Obstructive Pulmonary Disease 8.2%, creatinine 1.19±0.70, all at emergency department admission, in-hospital AKI 37.8%, Intensive Care unit admission 18.3%, and in-hospital death 20.6%. The main outcomes for the analysis of SNPs were in-hospital death, AKI and onset of proteinuria. The main findings for the SNP analysis concerned different genetic markers, each specific for different outcomes. A SNP in renin gene (REN), rs10900555, was associated with the in-hospital death (OR 3.84 [95%CI 1.58;9.25], P = .044), with the same risk alleles previously linked to salt-sensitive hypertension. TT genotype (at risk for salt-sensitivity) in uromodulin gene (UMOD, SNP rs4293393) increases the risk of proteinuria development (OR 1.86 [95%CI 1.02;3.40], P = .044). The genetic variants were selected as candidates for salt-sensitive hypertension and renal failure. Associations with genetic markers and outcomes were carried out with logistic regression analysis for outcome absence/presence comparison.

**Conclusion:** This genetic analysis, firstly reported on the COVID-BioB cohort, showed an intriguing relation between some polymorphisms previously associated with salt-sensitive hypertension and worst outcome or renal damage, during COVID-19. This genetic stratification may help to identify patients at risk AKI, and (directly or not) for death and renal damage (proteinuria) during COVID-19. Moreover, it may explain, at least in part, the debated relationship between hypertension and severity of COVID-19.

**TAKAYASU ARTERITIS IN THE TIME OF SARS-COV-2**

Pietro Finocchiaro1, Graziella Caridi1, Francesco Catalano1, Adele Postorino1, Rocco Tripepi2, Francesca Mallamaci1,2, Vincenzo Antonio Panuccio1,2

1 Grande Ospedale Metropolitano di Reggio Calabria, Nephrology, Dialysis and Transplantation Unit, Reggio Calabria, Italy and 2 Institute of Clinical Physiology - National Research Council, Clinical Epidemiology and Pathophysiology of Renal Diseases and Hypertension, Reggio Calabria, Italy

**Background and Aims:** SARS CoV 2 infection is characterized by pulmonary, cardiovascular, neurological and other complications. New onset hypertension after SARS CoV 2 infection was observed in various studies with an unclear mechanism. Vessel inflammation is a common finding in these patients.

**Case:** A young woman (24 years old) referred to our Unit for high blood pressure levels appeared few days after SARS COVID 2 infection. She had a positive familiar history of hypertension. A 24 hours blood pressure monitoring confirmed hypertension and the patient was treated with a beta-blocker and referred to the nephrologist. Physical examination was negative and peripheral pulses were palpable. Blood pressure was 150/90 mmHg without significant discrepancy (<10 mmHg) between right and left arm and between upper and lower limbs. Carotid-femoral and carotid-radial pulse wave velocity was in the upper limit of the normal range (9.8 and 8.0 m/sec respectively), renal function was preserved (serum creatinine 0.6 mg/dl, eGFR 154 ml/min) and proteinuria was 450 mg/die. C-reactive protein was 13 mg/L. Complement components C3 and C4 as well as IgG and anti-neutrophil cytoplasmatic antibody (ANCA) levels were in the normal range. IgA and IgM were slightly elevated and anti-nuclear antibody (ANA) levels were 1:160. TSH was in the normal range. Patient was switched to calcium channel blockers and a screening to exclude secondary hypertension was performed. Hormonal profile showed hypersecretion of cortex and medullary adrenal gland (high renin and aldosterone, plasma and urinary cortisol, and epinephrine levels). Patient was treated with ACE inhibitor and showed an optimal blood pressure profile. Abdominal-Chest CT angiography detected no increase in adrenal gland dimension. Conversely, a left renal artery stenosis and a mild enlargement of the para-aortic tissue, suggestive of a retroperitoneal fibrosis, was described (Figure 1). A Doppler ultrasound examination confirmed a high systolic peak velocity in left renal artery and a low resistive index in the left kidney. According to the diagnosis of renal fibrosis, patient was treated with oral prednisone at a dosage of 1 mg/Kg/BW. Three months later, Doppler ultrasound and CT were materially unchanged. After a case revision and a negative evidence of inflammation at PET-FDG examination, the Takayasu Arteritis diagnosis was formulated and the patient underwent left renal artery angioplasty. Oral prednisone was tapered and methotrexate was started. One month later blood pressure and Doppler ultrasound velocimetric parameters were normalized.

**Conclusion:** This case report suggests that Takayasu arteritis may occur after SARS COVID 2 infection.

**EFFECT OF RENAL DENERVATION ON THE PLASMA LEPTIN CONCENTRATION IN PATIENTS WITH RESISTANT HYPERTENSION**

Marcin Adamczak1, Beata Czerwienska1, Michal Lelek2, Damian Gojowy1, Katarzyna Mizia-Stec1 and Andrzej Jan Wiecek1

1 Medical University of Silesia, Department of Nephrology, Transplantation and Internal Medicine, Katowice, Poland and 2 Medical University of Silesia, 1st Department of Cardiology, Katowice, Poland

**Background and Aims:** Leptin is mainly produced by adipose tissue and has hypotensive properties. In patients with arterial hypertension, plasma concentration of leptin is higher than in healthy subjects. Percutaneous ablation of the sympathetic nervous system fibers located in the wall of the renal arteries by radio frequency waves (renal denervation - RDN), was introduced as a method of invasive treatment of resistant arterial hypertension. The aim of this single center, interventional, clinical study was to assess the effect of RDN on the plasma leptin concentration in patients with resistant arterial hypertension.

**Method:** Eighteen patients (9 women, 9 men) aged 53.2±6.5 years with resistant hypertension who underwent RDN using Simplicity catheters (Medtronic, Inc., Northridge, CA) before RDN denervation and 6 months after RDN. Additionally, patients were divided into two subgroups: responders (systolic and diastolic blood pressure - BP reduction 6 months after RDN >25

---

**F3 - PREVENTION, TREATMENT & CLINICAL TRIALS**

---

**Abstract**

---

**Figure 1:**
mmHg and > 12 mmHg, respectively; n=9) and low responders (systolic and diastolic BP reduction 6 months after RDN ≤25 mmHg and ≤12 mmHg, respectively; n=9).

**Results:** Systolic and diastolic BP was significantly reduced after RDN (196.6±28.2 and 162.9±15.6; p<0.001 and 117.9±26.4 and 90.7±8.6 mmHg; p<0.001, respectively). Body mass index (BMI) before RDN and 6 months after RDN did not change significantly in the entire studied group (27.2±14.3 and 24.6±13.1 [ng/mL], NS), as well as both in responders (29.5±14.4 and 28.2±12.9 [ng/mL], NS) and low-responders subgroups (24.4±14.7 and 21.0±12.9 [ng/mL], NS), respectively.

**Conclusion:** Renal denervation is effective in the treatment of patients with resistant hypertension, however this effect is not mediated by the influence on plasma leptin concentration.

**RENA MENAEMODYNAMIC PARAMETERS IN DIABETIC NEPHROPATHY**

Pavlos Malidretos¹, Nikolaos Anagnostou¹, Dimitrios Palaiologos¹, Kalliopi Tanou² and Georgios Koutroumpas¹

¹Achilleopouliou General Hospital, Nephrology Department, Volos, Greece and ²Achilleopouliou General Hospital, Pediatric Department, Volos, Greece

**Background and Aims:** Diabetic nephropathy is the leading cause of chronic kidney disease in modern world. Timely diagnosis is of paramount importance, especially after the recent introduction of novel therapies. The presence of an already altered renal haemodynamic profile was investigated in all patients referred with suspected diabetic nephropathy, upon their initial presentation to our renal department.

**Method:** During the past seven years, from January 2015 to December 2022, 578 patients were referred to the Renal Department for ultrasound assessment. Additionally to their standard assessment, they underwent renal ultrasound and triplex examination. Diabetic nephropathy (DN) was diagnosed in 149 patients. A group of patients with an estimated GFR> 60 ml/min, without diabetic nephropathy, was randomly selected from the same pull of patients for comparison reasons (control group). Renal haemodynamics assessment, including renal arteries, aorta and intrarenal resistive indexes (RI) of both kidneys, estimated glomerular filtration rate (CKDEPI) and 24h albuminuria, were evaluated in all patients.

**Results:** The mean age of the patients was 72.5 ±10.4 vs 65.8 ±6.9 years, for the DN and control group respectively. Renal length was comparable in both groups, renal diameter of left kidney was 10.61 ±1.28 vs. 10.59 ±1.44 cm and renal diameter of right kidney was 10.53 ±1.38 vs. 9.86 ±2.89 cm for DN group and control respectively. The estimated GFR was significantly lower in the DN group, 42.1±23.6 vs. 82.7 ±11.3 ml/min (p<0.05). Both renal arteries presented higher velocity values in the DN group, 53.4 ±22.2 vs. 21.7 ±28.9 cm/sec (p<0.0001) and 52.4 ±23.9 vs. 24.8 ±32.3 (p<0.0001), for the left and right renal artery. DN patients showed RI values above upper normal limit of 0.70, being at the same time significantly higher compared to control group, 0.73 ±0.06 vs. 0.61 ±0.17 (p<0.0001) and 0.72 ±0.06 vs. 0.59 ±0.20 (p<0.0001), for the left and right kidney respectively.

**Conclusion:** The presence of significantly increased renal artery velocity in diabetic nephropathy patients compared to control patients has not been described earlier to the best of our knowledge. It represents a new finding that is mainly attributed to the presence of arteriopathy. Evaluation of renal haemodynamics using triplex ultrasound, represents a non – invasive, readily available, inexpensive examination. When performed at initial patient presentation, constitutes an invaluable tool, timely assisting to diagnosis and treatment of diabetic patients.

**SALT SENSITIVITY AND HYPERTENSIVE NEPHROPATHY: A LINK TO BE DISCOVERED**

Chiara Livia Lanzi¹, Marco Simonini¹,²,³, Lorena Citterio², Laura Zagato², Luz Maria Gonzalez⁴, Francesca Tunesi³, Marianna Contursi¹, Paolo Maiuccchi¹, Paolo Manunta¹,²,³

¹IRCCS San Raffaele Scientific Institute, Division of Nephrology and Dialysis, Milan, Italy, ²IRCCS San Raffaele Scientific Institute, Genomics of Renal Diseases and Hypertension Unit, Milan, Italy, ³Università Vita Salute San Raffaele, Chair and School of Nephrology, Milan, Italy and ⁴Universidad de Extremadura, Dept. Medical Surgery Therapeutics, Badajoz, Spain

**Background and Aims:** Sodium sensitivity is defined as a change in blood pressure depending on sodium intake, which is present in about 30% of the adult population. According to blood pressure variation in salt load test we can classify the population in 3 categories: sodium sensitive (SS), sodium resistant (SR), inverse sodium sensitivity (ISS), based on, respectively, an increase, a non-significant variation or a decrease in the blood pressure values following the administration of sodium. It is reported that SS subjects have, independently from other risk factors, an increased risk of cardiovascular diseases. Moreover, SNPs located in genes related with Na+ metabolism, aldosterone synthesis and tubular sodium reabsorption in the kidney are related to salt sensitivity phenotype. The aim of this study is to analyze the relationship between sodium sensitivity and the development of hypertensive kidney damage in patients with primary hypertension.

**Method:** A cohort of 712 naïve hypertensive patients were classified for salt-sensitivity using acute saline test (NaCl 308 mEq/2h/iv).127 patients (follow-up > 5 years- median 11) were selected for the present analysis (SS, n= 40; 0 SR, n= 46; RSS, n= 41). We analyzed annual decline of the eGFR (CDK-EPI) (Delta-eGFR) and development of microalbuminuria (MicrAlb) as renal outcome. Moreover, genetic polymorphism involved in salt sensitive hypertension has been investigated.

**Results:** No differences in Delta-eGFR was observed among the groups. However, SR subjects develop earlier microalbuminuria (P = 0.002) even with an adequate pressure control. Genotypes analysis revealed: polymorphism in CYP11B2 and NEDD4L to be protective against decline in eGFR. For
Conclusion: Unexpectedly these finding suggests that SR patients are more at risk of developing hypertensive nephropathy than other groups of patients. Moreover genotypes associated with salt sensitivity play different and complex role in kidney damage in hypertension. Improvement in salt sensitivity testing and standardization will be needed to allow all this pathophysiological knowledge to be translated in a clinical setting.

CT-DERIVED RADIOMICS ANALYSIS OF DIABETIC NEPHROPATHY BY MACHINE LEARNING MODELS
Eui Seok Chung1, Eun Ji Lee1, Jongsin Yoon3, Haeyung Lee5, Hyongnae Kim5, Hyunjin Noh1, Soon Hyo Kwon1 and Jin Seok Jeon1
1 Soonchunhyang University Seoul Hospital, Division of Nephrology, Department of Internal Medicine, Seoul, Rep. of South Korea, 2 Soonchunhyang University Seoul Hospital, Department of Radiology, Seoul, Rep. of South Korea and 3 Severance Hospital, Yonsei University College of Medicine, Department of Radiology, Seoul, Rep. of South Korea

Background and Aims: Kidney radiomics has been used to develop more accurate diagnostic tools of renal tumor and predict outcomes. However, radiomics studies for diabetic kidney disease (DKD) remain few in this light. We hypothesized that computed tomography (CT) radiomics features could differentiate DKD from normal kidneys and assess the severity of DKD.

Method: This retrospective study included 343 subjects with type 2 diabetes mellitus (T2DM) (male 65.5%, mean age 63.6±14.8) and 90 healthy controls (HC) (male 34.4%, mean age 41.9±8.5) who underwent abdominal CT. Whole volumetric CT data of both kidneys were automatically extracted using a deep-learning based model and radiomics features were extracted. T2DM were categorized into three groups according to eGFR (mL/min/1.73 m²) (group 1, eGFR > 60; group 2, 15 < eGFR < 60; and group 3, eGFR < 15). The capability of CT radiomics features to distinguish not only DKD from HC but also various DKD groups based on eGFR, was evaluated using machine learning models.

Results: A total of 1,723 radiomics features were extracted from the volumetric CT data of both kidneys. A combination of LASSO filter and random forest showed the best performance in differentiating between HC and DKD with an area under curve (AUC) of 0.98 and accuracy of 95.7%. It also showed an excellent performance in differentiating between HC and DKD group 1 with AUC of 0.97 and accuracy of 91.7%, and also it was able to differentiate between DKD groups (AUCs > 0.78). CT radiomics features and eGFR had a moderate degree of correlation (R=−0.50 to R=0.63, all P<.001). This study suggests that radiomics features can be used to differentiate DKD from normal kidneys as well as assessing the severity of DKD.

#5423
THE FUNCTIONAL STATE OF THE KIDNEYS IN PATIENTS WITH CHRONIC ISCHEMIA OF THE RENAL AND PERIPHERAL ARTERIES
Gulchekra Atahodjajeva1, Botir Daminov2 and Norid Noradov2
1Tashkent Pediatric Medical Institute, Republican Specialized Scientific and Practical Medical Center of Nephrology and Kidney Transplantation, Internal Medicine, Nephrology and Hemodialysis, Tashkent city, Uzbekistan, 2Republican Specialized Scientific and Practical Medical Center of Nephrology and Kidney Transplantation, Internal Medicine, Nephrology and Hemodialysis, Uzbekistan and 3Tashkent Pediatric Medical Institute, Internal Medicine, Nephrology and Hemodialysis, Tashkent city, Uzbekistan

Background and Aims: to study the functional state of the kidneys in patients with chronic ischemia of the renal and peripheral arteries.

Methods: We examined 120 patients with chronic lower limb ischemia (CLLI) on the background of coronary heart disease and type 2 diabetes mellitus. All examined patients were hospitalized in the department of Interventional Cardiology of the Republican Specialized Scientific and Practical Medical Center for Therapy and Medical Rehabilitation. Inclusion criteria for the study was the presence of intermittent claudication in the patient of II A-II B degree of CLLI, while the walking distance without pain in these patients was 50-1000 meters. Assessment of the functional state of the kidneys was carried out on the basis of determining the level of serum creatinine (Cr), glomerular filtration rate (GFR), calculated according to the EPI GFR formula, which takes into account race, gender, age, and serum creatinine level. To calculate GFR using the CKD-EPI formula, can be used special applications for mobile devices (QxMD Calculator) (based on the criteria of the clinical guidelines for the diagnosis, classification and treatment of CKD KDIGO - 2013).

Results: Analysis of the functional state of the kidneys depending on the severity of CKD and the level of GFR in accordance with the KDIGO classification (2013) showed that all 100% of patients with CLLI belonged to CKD categories: CKD C2 - 62 (51.7%), CKD with 3a-b - 51 (42.5%) and CKD with 4 - 7 (5.83%). In other words, there was not a single patient with CLLI with normal GFR values. We have revealed a significant increase in the concentration of blood creatinine by 2.1 times, blood urea by 77.9%, and a decrease in GFR by 64.3% (p<0.001). The concentration of urea in the blood serum was 12.1±2.47 mmol/l in the CLLI group versus 6.8±0.33 mmol/l in the control group. The parameters of the functional state of the kidneys depending on the severity of CLLI showed that in the group of patients with stage IIB an increase in serum creatinine clearance by 47.2%, amounting to 179.2 ± 15.5 μmol/l versus the data of IIA 121,2±13.3 μmol/l (p<0.01). There was also a decrease in the level of GFR in patients with stage IIB by 29.1% (p<0.01) in relation to the data of stage IIA.

Conclusion: In all patients with CLLI, there was deterioration in the functional state of the kidneys, which was manifested by an increase in the concentration of blood creatinine, a decrease in GFR and the severity of albuminuria.

Background and Aims: Nephroangiosclerosis is a frequent renal disease due to chronic arterial hypertension and it is one of the main causes leading to renal replacement therapy. A minority of these patients have nephroangiosclerosis although they apparently have hypertension under control with minimal treatment.

Objectives: To describe the characteristics of this group of patients when compared to the rest of patients with histological diagnosis of nephroangiosclerosis.

Method: Observational, retrospective and descriptive study. Review of 67 patients with nephroangiosclerosis as the sole diagnosis in the renal biopsy (consecutive biopsies from 2010 to 2020). We divided the population in two different groups according to the number of prescribed antihypertensive drugs: Group 1 (0-1 antihypertensive drugs) vs Group 2 (≥2 antihypertensive drugs).

Results: Both groups had similar demographics and renal function/proteinuria. Both groups had the same adequate/inadequate blood pressure control, but group 1 had significantly less time of hypertension evolution. The histological differences (although not statistically significant) are noteworthy: Group 1 had a higher percentage of global glomerulosclerosis, interstitial fibrosis and tubular atrophy than Group 2. In addition, after 3-years of follow-up, in Group 1 there were more patients requiring renal replacement therapy. We hypothesize that a factor that could explain these results could be the lower use of RASIs (33.3% vs 73.9%, P = .003) and a higher percentage of history of dyslipidemia in Group 1 (62.5% vs 22.2%, p=0.017*).

Conclusion: Patients with hypertension requiring a maximum of one drug for its control, presented histological results of more marked nephroangiosclerosis, than the group of patients with more than one drug, despite similar time of evolution and degree of blood pressure control. These findings could be related to a lower rate of RASi use. Our study reinforces the indication for RASi as a first-line hypertension treatment in this population.

**KIDNEY TRANSPLANTATION IN EARLY PREGNANCY-ASSOCIATED ATYPICAL HEMOLYTIC UREMIC SYNDROME**

Michael Che¹, Sarah Moran², Richard Smith³ and Jocelyn Garland⁴

¹University of Ottawa, Department of Medicine, Ottawa, Canada, ²University College Cork, Department of Nephrology, Cork, Ireland, ³Roy J. and Lucille A. Carver College of Medicine, Molecular Otologyngology and Renal Research Laboratories, Iowa City, United States of America and ⁴Queen’s University, Department of Medicine, Kingston, Canada

**Background and Aims:** Clinical differentiation of pregnancy-associated thrombotic microangiopathies is challenging and can occur in conjunction with or mimic conditions including hemolysis, elevated liver enzymes, low platelet count (HELLP syndrome), pre-eclampsia (PET), thrombotic thrombocytopenia purpura (TTP) and atypical HUS (aHUS). aHUS that occurs during pregnancy classically presents in the third trimester. When kidney transplantation is performed in aHUS patients, disease recurrence is high and can be associated with transplant failure. Here, we report a unique case of aHUS that presented early during pregnancy where the patient subsequently underwent kidney transplantation.

**Method:** We present a case report. Ethics approval was obtained by the Queen’s University Health Sciences and Affiliated Teaching Hospitals Research Ethics Board.

**Results:** A 30 year old G2P0A1 diabetic African American woman presents at 9 weeks gestation with new hypertension. At 18 weeks, she developed acute kidney injury and proteinuria. Further investigations revealed hemoglobin 68 g/L, platelets 120 x 10⁹/L, increased LDH 588 U/L, undetectable haptoglobin and schistocytes on blood smear. Creatinine was 88 umol/L, increased from a baseline of 50 umol/L, and proteinuria greater than 1 g/day. Pre-eclampsia was ruled out as her presentation began at 9 weeks gestation, prior to placentation implantation. Placental growth factor levels at 24 and 28 weeks remained >100 pg/mL. HELLP syndrome was excluded given the timing in pregnancy and normal liver enzymes. TTP was excluded with a normal ADAMTS13. Complement Factor H autoantibody was negative. Complement studies revealed grossly elevated soluble C5b-9 level (sC5b-9) of 1.05 (normal <0.3 mg/L). aHUS was diagnosed and she began treatment with eculizumab (ECU). Ex-vivo serum C5b-9 deposition on human microvascular endothelial cells was assessed and was severely abnormal pre-treatment with ECU (activated 223%, normal <150%), and normalized with ECU therapy (activated 123%, normal <150%). Genetic testing eventually revealed a Complement Factor I mutation, NM_000204.3:c.550G/A, p.Vall84Met reported as likely pathogenic.

**Conclusion:** aHUS, although described to occur late in pregnancy or post-partum, remained on ECU and had excellent graft function without proteinuria (urine ACR 2.2 mg/mmol) or evidence of aHUS recurrence.
is not always PET or HELLP. aHUS is a treatable condition in pregnancy, and should be considered as a possibility particularly for presentations occurring prior to 20 weeks gestation. Complement function studies may aid in aHUS diagnosis. Despite extra ECU dosing and therapeutic ECU levels for this patient and kidney transplantation, she had evidence of massive C5 release (grossly elevated sC5b-9 level). sC5b-9 measurement posttransplantation may be useful to guide ECU dosing.

SYSTEMATIC REVIEW AND META-ANALYSIS OF THE SAFETY AND EFFICACY OF NON-STEROIDAL ANTI-INFLAMMATORY DRUGS FOR THE MANAGEMENT OF POSTPARTUM PAIN
Arunima Jain1, Lauren Heath1, David Tian2,3, Sai Sirittharan1, Florencia Natali1, Mudith Jayasekara1, Lauren Thurgate1, Sean Seeho1, Anthony Delaney1,2 and Amanda Mather1
1Royal North Shore Hospital, Department of Renal Medicine, Sydney, Australia, 2Westmead Hospital, Department of Anaesthesia and Perioperative Medicine, Sydney, Australia, 3University of Melbourne, Melbourne, Australia, 4University of Sydney, Medical School, Sydney, Australia, 5Royal North Shore Hospital, Department of Intensive Care Medicine, Sydney, Australia, 6Women and Babies Research, Kolling Institute, Faculty of Medicine and Health, Sydney, Australia and 7George Institute for Global Health, Division of Critical Care, Sydney, Australia

Background and Aims: Effective pain management is critical for postpartum recovery. While commonly prescribed, systematically reviewed data regarding efficacy of non-steroidal anti-inflammatory drugs (NSAIDs) are limited. Moreover, guidelines suggest avoiding NSAIDs in women with hypertensive disorders of pregnancy (HDP) due to risks of hypertension and adverse events (AE). However, these AE have not been consistently observed in cohort studies following postpartum NSAID use. This systematic review aims to provide further insight into the postpartum safety and efficacy of NSAIDs.

Method: A systematic review of eight databases and four clinical trial registries was conducted in July 2020 (PROSPERO Protocol CRD42020196054). RCTs which assessed the safety and/or efficacy of NSAIDs in postpartum women after the year 2000 were included. The primary outcome was incidence of hypertension, with secondary outcomes categorised into three groups: hypertension, secondary safety and efficacy. Data were tabulated and analysed using R (version 4.0.2). Due to heterogeneity in study design, NSAIDs were grouped based on mechanism to facilitate meta-analysis. Risk of bias was assessed using the RoB 2 tool with a plan to assess quality of evidence for the primary outcome.

Results: 12,172 records were identified with the inclusion of 92 RCTs. Eight studies, with four that included women with HDP, reported hypertension-related data (Table 1). The primary outcome was included in one RCT. Secondary safety outcomes such as acute kidney injury or eclampsia were not reported. The odds of nausea, vomiting and sedation were similar between groups. NSAIDs were effective when compared with placebo, as assessed by mean differences (MD) in visual assessment scores (VAS) at 12 hours (MD -1.57, 95% confidence intervals (CI) -2.47 to -0.66), 24 hours (MD -0.82, 95% CI -1.42 to -0.22) and need for additional analgesia (odds ratio 0.17, 95% CI 0.05 to 0.61). There were no significant differences in VAS between NSAIDs and other comparators at 12 and 24 hours. Further interpretation of results is limited due to heterogeneity in intervention and comparator groups, inclusion criteria and reported outcomes.

Conclusion: Our study confirms the efficacy of NSAIDs for postpartum pain, but current data are inconclusive regarding the risk of developing hypertension. Available data do not demonstrate trends toward AE although further research is required to determine long term, clinically-relevant outcomes to guide decision making.

*HTN = hypertension; CS = caesarean; V = vaginal; PET = preeclampsia; HELLP = haemolysis, elevated liver function tests, and low platelets; CHTN = chronic HTN; gHTN = gestational HTN; ND = no difference; BP = blood pressure; sBP = systolic BP; dBP = diastolic BP; HDP = hypertensive disorders of pregnancy; antiHTN = antihypertensive; MAP = mean arterial pressure
how many pregnancies are affected is not well known. This study aimed to evaluate the burden of CKD and associated birth rates in an entire region. **Method:** This was a retrospective cohort study including women of childbearing age in Stockholm during 2006–2015. We estimated the prevalence of CKD by the presence of an ICD-10 diagnosis of CKD, a single estimated glomerular filtration rate (eGFR) < 60 mL/min/1.73 m² or history of maintenance dialysis. By linkage with the Swedish Medical Birth Register we identified births during the subsequent three years from study inclusion and evaluated birth rates. For CKD prevalence, we reported overall counts and the age-averaged prevalence to adjust for the uneven age distribution in the cohort. A linear regression model was fitted to identify the increase in prevalence and 95% confidence interval (CI) per additional year in age. Birth rate was calculated per 1000 person years. All analyses were performed using R version 4.2.1. **Results:** We identified 817,730 women in our region, of whom 55% had at least one creatinine measurement. A total of 3938 women were identified as having CKD, providing an age-averaged CKD prevalence of 0.50%. Women with probable CKD showed a lower birth rate 3 years after the index date (35.7 children per 1000 person years) than the remaining women free from CKD (46.5 children per 1000 person years). **Conclusion:** As many as 0.50% of individuals in this cohort had CKD, defined on the basis of at least one eGFR<60 mL/min/1.73 m² test result, dialysis treatment (i.e. CKD stages 3–5) or an ICD-10 diagnosis of CKD. This prevalence is lower than previous estimates. Women with CKD had a lower birth rate than those without CKD, illustrating the challenges of this population to successfully conceive. Future research should be done to identify impeding factors.

**AKI & CRITICAL CARE NEPHROLOGY**

## #3419 LINARIN PROTECTS THE KIDNEY FROM ISCHEMIA-REPERFUSION INJURY AND SUPPRESSES ETS2 INDUCED ACUTE KIDNEY INJURY

Chengyu Yang
The Affiliated Hospital of Qingdao University, Department of Nephrology, Qingdao, P.R. China

**Background and Aims:** Ischemia/reperfusion injury (IRI), a participant in acute kidney injury (AKI), can occur as a series of pathological processes such as inflammation. Linarin (LIN) has been widely used for different diseases. To confirm the anti-inflammatory value and relevant mechanism of LIN during IRI, in vivo and vitro model were established. **Method:** LIN or isovolumetric DMSO was given, and histologic analysis, quantitative real-time reverse transcription polymerase chain reaction (qRT-PCR), serum creatinine (SCr) testing and blood urea nitrogen (BUN) were used to evaluate kidney injury. Microarray analysis, protein–protein interaction (PPI) analysis and molecular docking were used to identify target protein of LIN. **Results:** At first, we find that LIN could inhabbit the kidney injury in vivo IRI model and decrease the expression of IL-12 p40 in vitro IRI model. To explore the mechanism of LIN, we collected raw data from public microarray database and identified E26 oncogene homolog 2 (ETS2) as a target protein of LIN according to microarray analysis, PPI and molecular docking. The contact area is highly conserved and located on a protein–protein interaction domain of ETS2 which indicated that LIN may alter the interaction with synergistical protein in the regulation of IL-12 p40 expression. **Conclusion:** Our study demonstrated the anti-inflammatory effect of LIN during IRI-triggered AKI, broadening the medicinal value of LIN and the therapeutic options for IRI-triggered AKI.
Figure 1: LIN protect kidney from IRI in vivo.

Figure 2: Effects of LIN on HK2 cells.

Figure 3: Volcanic plot of microarray data.
Background and Aims: Acute kidney injury (AKI) is a major medical complication associated with a markedly increased risk of death, particularly in patients admitted to the ICU where in-hospital mortality exceeds 50%. This study aimed to determine the accuracy of MPV, platelet count, and PDW as predictors of adverse outcomes in patients with AKI who received initiation renal replacement therapy (RRT).

Method: A retrospective cohort single-center study was done in a local private tertiary hospital in Cebu. Four hundred ninety-one patients with AKI who underwent RRT between January 2018 and December 2021 were enrolled. A retrieval of data on demographic and clinical parameters during the initiation of RRT was done. The impact of mortality-related factors were identified using univariate and multivariate logistic regression analysis. Determination of optimal cut-off values of platelet indices for in-hospital mortality was done.

Results: This study showed that the in-hospital mortality of patients was 58.45%, with a mean age of 68.6 ± 16.28 years among non-survivors. Among the platelet indices, platelet count and PDW were good predictors of in-hospital mortality in patients who received initiation renal replacement therapy. The optimal cut-off value of platelet count was 173 x 103/uL (sensitivity 56.45%, specificity 62.25%, PPV 67.78%, NPV 50.40%, AUC 0.604). The optimal cut-off value of PDW was 16.45% (sensitivity 50.87%, specificity 71.57%, PPV 71.57%, NPV 50.87%, AUC 0.611).

Conclusion: Platelet indices are feasible parameters that can be used as prognostic markers for mortality in patients with AKI requiring RRT. The in-hospital mortality of patients with AKI requiring initiation RRT is high (58.45%). Low platelet counts, high MPV values, and high PDW values are associated with poorer outcomes and higher mortality risk as compared to patients with normal indices.
CHARACTERIZATION OF KIDNEY FUNCTIONAL DAMAGE ASSOCIATED TO CO-TREATMENT WITH IMMUNE CHECKPOINT INHIBITORS AND CISPLATIN

Javier Tascón1, Alfredo G. Casanova1, Laura Vicente-Vicente1, Moisés Pescador1, Marta Prieto1, Ana Isabel Morales Martín1,2,3

1Universidad de Salamanca, Salamanca, Spain, 2Institute for Biomedical Research of Salamanca (IBSAL), Salamanca, Spain and 3Translational Research on Renal and Cardiovascular Diseases (TRECARD), Salamanca, Spain

Background and Aims: Advances in the knowledge of the immune response against tumors and the evasion mechanisms of these have led to develop new cancer therapies focused on improving the immune response and thus increasing patient survival. This is the case of immunotherapeutic treatment based on immune checkpoint inhibitors (ICI). However, treatment based on these antibodies is associated with autoimmune side effects, in most of the body organs, that limit their use. Although nephrotoxicity is rare, renal effects have been shown to worsen the prognosis of cancer patients. Recently, therapies based on the combination of immuno and chemotherapy have been approved. They have improved efficacy but have increased the risk of suffering nephrotoxic adverse effects. Our hypothesis is that kidney damage associated with ICIs could be subclinical and not evidenced by the parameters used in clinical practice (mainly plasma creatinine). The aim of this work was to characterize functional kidney damage associated with ICI (anti-CTLA-4) in combination with chemotherapy (cисплатин) in a murine model.

Method: C57BL/6 mice were treated with combined therapy of cisplatin (10 mg/kg, single dose) and anti-CTLA-4 (10 or 15 mg/kg/day, for 6 days) administrated by intraperitoneal injection. In addition, groups treated with drug monotherapies and a control group were included. Urine and blood samples were collected at baseline, on day 3 and on day 6 (sacrifice). Biomarkers of subclinical kidney damage were determined by ELISA in urine samples. There were albumin, neutrophil gelatinase-associated lipocalin (NGAL) and kidney injury molecule 1 (KIM-1). Blood samples were centrifuged to obtain plasma, in which creatinine and urea were measured using colorimetric techniques. Data were analyzed with the statistical software SPSS®.

Results: Plasma creatinine and urea were elevated in the combined therapy group with respect to monotherapies and control group. Multivariate logistic regression analysis showed that serum bicarbonate concentration on admission remained significant predictors of AKI in patient with glufosinate poisoning.

Conclusion: Serum bicarbonate is helpful to predict the development of patients with glufosinate poisoning.

CLINICAL CHARACTERISTICS OF ACUTE KIDNEY INJURY IN PATIENTS WITH GLUFOSINATE POISONING

A Young Cho, In O Sun and Ju Hwan Oh

Presbyterian Medical Center, Division of Nephrology, Department of Internal Medicine, Jeonju, Rep. of South Korea

Background and Aims: Glufosinate-containing herbicide is widely used in agriculture. According to previous reports, glufosinate poisoning causes various complications, but there are few reports of nephrotoxicity. In this study, we investigated the incidence and clinical characteristics of acute kidney injury (AKI) in patients with glufosinate poisoning.

Method: This study performed between 2008 and 2021 included 76 patients categorized into the AKI and the non-AKI groups. The incidence, clinical characteristics, and severity of AKI were compared between the AKI (n=54) and the non-AKI (n=22) groups, based on the Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease classification.

Results: The incidence of AKI was 71.1%, of which 40.9%, 26.3%, and 3.9% patients were classified into the Risk, Injury, and Failure categories, respectively. Patients in the AKI group were older (62.6±14.2 years vs. 54.9±16.2 years, P=0.045) and poorer renal function (73.9±25.2 mL/min/1.73 m² vs. 94.5±35.5 mL/min/1.73 m², P=0.006) on admission. The length of hospitalization was longer (17.2±17.2 days vs. 7.6±7.6 days, P=0.014) in AKI group, and the mean amount of glufosinate ingested was higher in AKI group than that in non-AKI group (250±172 mL vs. 152±121 mL, P=0.032). In addition, the serum bicarbonate level was lower in AKI group than in non-AKI group (19.9±4.7 vs. 23.0±3.3, P=0.006). Notably, intensive care unit admissions (81.5% vs. 40.9%, P=0.001) and mechanical ventilator support (68.5% vs. 22.7%, P<0.001) were more frequently required in the AKI group. Multivariate logistic regression analysis showed that serum bicarbonate concentration on admission remained significant predictors of AKI in patient with glufosinate poisoning.

Conclusion: Serum bicarbonate is helpful to predict the development of patients with glufosinate poisoning.

5301

COVID-19 AND ACUTE KIDNEY INJURY IN ELDERLY PATIENTS: A COMPARATIVE COHORT STUDY BETWEEN THE FIRST AND SECOND WAVE OF THE PANDEMIC IN BRAZIL

Bruna Yuasa, Luis Magalhães, Paula Gabriela Sousa de Oliveira, Laís Yokota, Pedro Cardoso, Welder Zamoner, Andre Balbi and Daniela Ponce

Faculty of Medicine of Botucatu, UNESP, Brazil

Background and Aims: In the different waves of the pandemic caused by the SARS-CoV-2 virus, the elderly continued to be affected with more severe cases
of the disease and possible progression to death. The objective of this study was to
evaluate the incidence of acute kidney injury (AKI) in the elderly during the first and second waves of the pandemic in Brazil, the risk factors associated with its development and death.

Method: Retrospective cohort study that evaluated patients over 60 years of age admitted to a Public, Tertiary, and Reference Hospital for COVID-19 with a diagnosis of SARS-CoV-2 infection, from March to December/2020 (first wave), and from January to May/2021 (second wave), from admission to hospital outcome (death, dialysis discharge or death).

Results: Throughout the entire period, 434 elderly patients diagnosed with COVID-19 were admitted, 173 in the first wave and 261 patients in the second wave. These two groups of patients were similar in terms of age (71±8.41 vs 70±8.32, p = 0.3329), need for intensive care unit admission (56.1% vs 58.2%, p = 0.655), vasoactive drug use (43.9% vs 52.9%, p = 0.686), need for mechanical ventilation (43.4% vs 52.5%, p = 0.062), higher APACHE values (19.7±5.3 vs 17 ±±5.64, p = 0.312), SOFA (9.4±7.07 vs 7±5.36, p = 0.332), CPK (95±570.75 vs 150±4830.47, p = 0.0886), the incidence of AKI (56.6% vs 58.6%, p = 0.684) and mortality (46.8% vs 55.2%, p = 0.088). However, they differed in terms of white race (77.3% vs 86.8%, p = 0.01), use of corticosteroids (56.6 vs 93.9%, p = 0.001), presence of proteinuria (44.8% vs 58.2%, p = 0.031), higher values of ATN-ISS (0.76±0.23 vs 0.86±0.21, p = 0.004) and D Dimer (5098.6±5995.04 vs 2436.5±8398.38, p = 0.0147). The two waves were similar regarding the following factors associated with the development of AKI: higher baseline creatinine, CPK, and D-Dimer values during hospitalization, higher APACHE values, need for mechanical ventilation, use of vasoactive drugs, presence of proteinuria and hematuria in the urine on hospital admission. There was a difference in terms of the waves regarding males (47.40% vs 46.08%, p = 0.037), a relevant factor in the development of AKI in the first wave; while the presence of SAH (63.9% vs 77.8%, p = 0.002), the use of ACEIARB (42.6% vs 56.2%, p = 0.0412) and the filtration rate basal glomerular (91±29.61 vs 80±5±26.79, p = 0.0021) were observed as factors associated with AKI only in the second wave. In the logistic regression of both waves, mechanical ventilation remained a risk factor for the development of AKI. In the first wave, the highest baseline creatinine value was also maintained as a risk factor (OR 10.5, CI 1.22-90.61, p = 0.032); while in the second, SAH (OR 1.646, CI 1.150-1.839, p = 0.018), hematuria (OR 1.681, CI 1.124-1.882, p = 0.018) and higher value of D Dimer (OR 1.977, CI 2.000-2.003, p = 0.023) remained as relevant factors for the development of AKI. As factors associated with mortality in the first wave, the highest value of CPK (OR 1.009, CI 1.001-1.017, p = 0.042) and the need for mechanical ventilation (OR 17.71, CI 1.13-277.62, p = 0.002) in the second wave, the factors associated with death were the presence of DM (OR 4.875 CI 2.602-7.094, p = 0.001), ARF (OR 1.858, CI 1.070-1.287, p < 0.001), need for dialysis (OR 1.813, CI 1.086-1.407, p = 0.001), proteinuria (OR 1.968, CI 1.142-1.913, p = 0.032) and higher ATN- ISS value (OR 5865.316, CI 1.325-25967740, p = 0.043).

Conclusion: The incidence of AKI was similar between the two waves of the pandemic; however, its severity was greater in the second wave, in which it was identified as a factor associated with death. Despite the greater severity of AKI, evidenced by the higher ATN-ISS, there was no higher patient mortality during the second wave of the pandemic.

#3235
ELECTROLYTE DISORDERS IN COMMUNITY-ACQUIRED ACUTE KIDNEY INJURY
Jose Maria Peña Porta, Paula Juarez Mayor, Mireia Pujol Saumell, José Antonio Ferreras Gascó, Axenia Babara and Pablo Iñigo Gil
Hospital Clínico Universitario Lozano Blesa, Nephrology, Zaragoza, Spain

Background and Aims: The kidney plays a decisive role in regulating the homeostasis of the internal environment. Acute kidney injury (AKI) compromises the kidney’s ability to maintain this regulation intact, and the appearance of various electrolyte disorders in this situation is frequent. There are few data in the literature that describe these alterations in patients with community-acquired AKI (CA-AKI). The purpose of this study is to analyze the incidence of electrolyte disorders in a cohort of patients with CA-AKI admitted to the nephrology service of a tertiary level hospital.

Method: This is a single-center, observational, longitudinal, and retrospective study based on a cohort of patients with CA-AKI admitted to the Nephrology Service of a third level hospital from January 2010 to December 2018. We analyzed the incidence of changes in sodium, potassium, chloride, bicarbonate, calcium, and phosphorus in these patients and their clinical consequences during admission and follow-up after hospital discharge.

Results: A total of 693 patients were included in the final analyses. The mean age was 72±13.1 years. Charlson comorbidity index was 5.87 ±2.4 points. The length of stay was 11.6±10.14 days. In view of the Etiology of AKI, 72.1% had prerenal AKI and 27.9% non-prerenal. 436 patients had a history of previous chronic kidney disease (CKD) (68.23%), AKI KDIGO stages were: stage I, 105 cases (16.4%); stage II, 67 cases (10.5%); stage III 467 cases (63.1%). Hemodialysis (HD) was required in 114 patients (17.8%). 62 patients (9.7%) died during hospital stay. The percentage of patients with alterations in the different ions was: chloride 54%, potassium 60.1%, sodium 45.23%, bicarbonate 85.67%, calcium 52.68%, phosphorus 54.49%. The most frequent ionic alterations at a global level were low bicarbonate (78.3%), hyperkalemia (53.03%), hypocalcemia (49.6%) and hyponatremia (49.49%). These alterations were significant different when comparing patients with previous CKD with respect to carriers of normal baseline renal function (glomerular filtration rate > 60 ml/min). When analyzing whether electrolyte alterations occurred simultaneously: 2.2% of cases did not present any, 6.3% only one, 18.2% two, 26.4% three, 26.1% four, 14.9% five and 5.9% six simultaneous alterations. In the univariate analysis, patient age (OR 1.977, CI 22.7; p = 0.001), hyperkalemia (Chi square 9.7; p = 0.008) and hyperphosphatemia (Chi square 18.5; p < 0.001) had higher mortality during admission. In the multivariate analysis using logistic regression, the variables that were independently associated with mortality during hospitalization were phosphorus (OR 1.425; 95% CI 1.212 - 1.676) and chloride (OR 1.045; 95% CI 1.002 - 1.089). In the follow-up after hospital discharge, the Kaplan-Meier curves in the univariate analysis showed higher mortality in patients who presented hyperkalemia (log rank test: Chi square 15.5; p = 0.0001), hypernatremia (log rank test: Chi square 47.7; p < 0.0001), hypocalcemia (log rank test: Chi square 6.73; p < 0.034) and hyperphosphatemia (log rank test: Chi square 10.24; p < 0.006). In the multivariate analysis using Cox regression, the variables that were independently associated with mortality after hospital discharge were sodium (Exp(B) 1.001; 95% CI 1.002 - 1.048; p = 0.048), potassium (Exp(B) 1.140; 95% CI 1.055 - 1.233; p = 0.001) and phosphorus (Exp(B) 1.087; 95% CI 1.023 - 1.048; p = 0.154).

Conclusion: In our series of patients with CA-AKI, we detected a high prevalence of electrolyte disorders, without a history of previous CKD having any influence on it. The most frequent was the finding of three or four simultaneous alterations. Phosphorus and chloride independently influenced mortality during admission. In the follow-up after hospital discharge, sodium, potassium, and phosphorus were independent predictors of mortality. The clinician who treats cases of CA-AKI must expect the appearance of frequent electrolyte disorders and must be prepared for their correct management.
during their stay in ICU none during treatment with TPE, all of them were diagnosed to have severe sepsis as a cause of death.

Conclusion: According to our experience, membrane therapeutic plasma exchange is a successful and secure treatment for a variety of illnesses including thrombotic microangiopathies, systemic vasculitis, myasthenia gravis, proliferative lupus nephritis, and Guillain-Barré syndrome. The main reason for death was sepsis.

A STUDY OF ETIOLOGY OF ACUTE KIDNEY INJURY AND ACUTE ON CHRONIC KIDNEY DISEASE AMONGST IN-HOSPITAL PATIENTS IN A TERTIARY CARE CENTRE IN INDIA

Sayonee Das¹, Upal Sengupta² and Dr Satyabrata Ganguly³

¹KPC Medical College & Hospital, General Medicine, Kolkata, India. ²KPC Medical College & Hospital, Nephrology, Kolkata, India and ³KPC Medical College & Hospital, General Medicine, Kolkata, India

Background and Aims: Acute kidney injury (AKI) is the leading cause of nephrology consultation and is associated with high mortality rates. The primary causes of AKI include sepsis, ischemia, hypoxia or nephrotoxicity. An underlying feature is a rapid decline in GFR usually associated with a decrease in renal blood flow. Inflammation represents an important additional component of AKI leading to the extension phase of injury, which may be associated with insensitivity to vasodilator therapy. Recent data suggest that AKI represents a potential link to chronic kidney disease (CKD) in surviving patients. Patients with CKD may be at risk for the development of a transient decrease in renal function consistent with AKI. Such rapidly declining renal function causing an acute deterioration of CKD is termed acute-on-chronic kidney disease (ACKD). The mechanisms by which these occur include failure of auto-regulation, abnormal vasodilatation, susceptibility to antihypertensive agents & side effects of medication. The successful recovery from AKI depends on the degree to which these repair processes ensue & these may be compromised in elderly or CKD patients.

Aim: To determine the burden of AKI among the in-hospital patients & their progression to CKD if at all along with the number & cause of the cases of CKD who develop ACKD due to an acute insult.

Method: The first 100 consecutive patients admitted with Acute Kidney Injury and Acute on Chronic Kidney Disease in the Department of General Medicine, Nephrology, Intensive care unit in KPC Medical College & Hospital, Kolkata, were selected for the study.

Inclusion criteria:
- Patients admitted with AKI, ACKD or developing them during the course of stay.
- CKD stages I to V with acute exacerbation (reduced GFR, reduced urine output).

Exclusion criteria:
- Patients <14 years
- ESRD patients already on hemodialysis.
- Patients with acute Glomerulonephritis (due to the unavailability of biopsy in our institution)
- Patients not giving consent to participate in the study.

For statistical analysis, data were entered into an Microsoft excel spreadsheet and then analyzed by SPSS and GraphPad Prism version 5. Data had been summarized as mean and standard deviation for numerical variables and count and percentages for categorical variables. Unpaired proportions were compared by Chi-square test or Fischer’s exact test, as appropriate. p-value 0.05 was considered statistically significant.

Results:

</table>

Clinically significant (P = .0197).

- Out of the first 100 consecutive patients fulfilling the study criteria, 33 patients had AKI & 15 patients had ACKD.
- The male population was higher than the female population.
- T2DM and HTN were more common in ACKD patients than the AKI patients.
- Patients with AKI were clinically dehydrated compared to patients with ACKD.
- Most of the ACKD patients had sepsis than the AKI patients.
- Conclusion: The most common etiology of AKI amongst in-hospital patients is dehydration whereas that of ACKD is sepsis associated with more incidence of metabolic acidosis & comorbidities. Earlier diagnosis of AKI represents an important area in treating patients with AKI that has spawned increased awareness of the potential that biomarkers of AKI may play in the future.

#3740

AFTER ALL A TYPICAL HUS

Helena Vidal, Maria Do Mar Menezes, Nuno Moreira Fonseca and Cristina Jorge

Hospital Curry Cabral, Nephrology, Portugal

Background and Aims: Typical Hemolytic Uremic Syndrome (HUS) is a thrombotic microangiopathy (TMA) characterized by the triad of acute renal failure, hemolytic anemia and thrombocytopenia. TMA are classified into three types: Inherited or primary acquired (atypical HUS), secondary or infection associated. Infection with Shiga-toxin–producing Escherichia coli (E. coli), mainly of serotype O157:H7, is the most common cause of typical HUS, but other serotypes have been rarely associated such as Enteraggregative Escherichia coli (EAE) serotype O104:H4.

Method: Case Report

Results: We report a case of a 51-years-old male with past medical history of arterial hypertension (treated with Perindopril) and IgG Multiple Myeloma (MM) diagnosed 10 years prior submitted to two bone marrow autotransplants (9 and 4 years prior) and multiple chemotherapy agents including Carfilzomib–Pomalidomide-Dexamethasone (last cycle 4 days before the onset of symptoms). One week after returning from a trip to Brazil, he was admitted to the emergency department with a two-day history of non-bloody diarrhea (≥5 liquid stools per day) and asthenia, with similar positive familiar epidemiology. He denied abdominal pain, fever, nausea or vomiting. At physical examination, he was hypertensive (177/90 mmHg), anuric (12.5 ml/h), dehydrated and apyretic. Abdominal palpation was painless and there were no signs of peritoneal irritation. Laboratory tests showed hemoglobin 10.5 g/dl, new onset thrombocytopenia (261 000/uL » 21 000/uL), kidney dysfunction (serum creatinine (SCr) 0.74 mg/dL to 9 mg/dL and serum urea (SU) 41 mg/dL to 260 mg/dL), hyperkalemia (6 mEq/L) and metabolic acidosis (pH 7.39 and bicarbonate 18.4 mEq/L). LDH was 1949 U/L, C-reactive protein 30.6 mg/L, procalcitonin 3.77 mg/mL, haptoglobin <0.07 g/L and with normal complement levels (C3 and C4). Schistocytes were present in peripheral blood smear. The diagnosis of Acute Kidney Injury related with TMA was established and the patient was transferred to the Nephrology ward and urgent hemodialysis was started. Exhaustive study was performed showing normal renal ultrasound, non-nephrotic proteinuria (1.6 g/g), urinalysis showed leukocyturia and erythrocyturia. Autoimmune study including PR3-ANCA, MPO-ANCA, anti-GBM antibody, anti-dsDNA antibody, anti-beta 2-glycoprotein I antibodies, antiphospholipid antibodies, anti-ADAMTS13 antibodies and ADAMTS13 activity, as well as study of complement C3, C5, C4, factor B, H and I, anti-factor H ac. AH 50 and CH50b were unremarkable. Blood and urine culture and antistreptolysin O titers were negative. Specific stool cultures for E. coli O157, Shigella, Salmonella, Yersinia and Campylobacter were negative. Stool evaluation for parasites were
also negative. Viral serology for HIV, HBV, HCV and Plasmodium tests were negative. PCR stool was required due to high suspicion of E.coli infection. The suspicion of a Carfilzomib induced TMA was also raised, while molecular techniques results were awaited. MM was stable and treatment was held until recovery of kidney function. During hospitalization the patient recovered diuresis and creatinine decreased. On the 11th day of hospitalization, he was discharged but still depended on hemodialysis. Finally, stool PCR techniques identified aatA and aggR genes associated with EAEC O104:H4 allowing the diagnosis of acquired infectious HUS rather than drug-related TMA. One week after discharge, the dialysis was stopped due to sCr 3 mg/dL. Four months later, he resumed Carfilzomib and kidney function remained stable with sCr 0.9 mg/dL, despite sustained proteinuria of 1.2 g.

Conclusion: The authors emphasize the importance of considering other causes of TMA when E.coli O157 infection is excluded, namely drug-related causes (as Carfilzomib) or less frequent infectious agents such as EAEC O104:H4. This case reveals the importance of requesting PCR in the stool even when the E.coli test is negative. This is of particular relevance in immunosuppressed patients. This diagnosis allowed continuing MM treatment.

#5395
ASSOCIATION BETWEEN PARABEN EXPOSURE AND EARLY RENAL INJURY IN A MIDDLE-AGED ADULT IN TAIWAN
Jung-Wei Chang¹, Yen-Hsuan Huang¹, Hsin-Chang Chen², Wan-Ting Chang¹ and Po-Chin Huang³

1Institute of Environmental and Occupational Health Sciences, National Yang Ming Chiao Tung University, Taipei, Taiwan, Rep. of China, ²Tunghai University, Department of Chemistry, Taichung, Taiwan, Rep. of China and ³National Health Research Institutes, National Institute of Environmental Health Sciences, Miaoli, Taiwan, Rep. of China

Background and Aims: Parabens are a class of preservatives used in the cosmetics industry and are widely used in people's daily lives, including personal care products (PCPs), pharmaceuticals and food. Epidemiological studies concerning the relations of exposure to parabens with renal function were limited. We aimed to investigate the potential sources of paraben exposure, estimate the daily intake (DI) of four parabens based on their urinary levels and the association between urinary paraben and renal function in a middle-aged adult population in Taiwan.

Method: We recruited 591 subjects aged from ≥40 to <65 years old (yrs) who have participated in Taiwan Environmental Survey for Toxicants (TEST) study from 2013-2016. Urinary parabens including methylparaben (MeP), ethylparaben (EtP), propylparaben (PrP), and butylparaben (BuP) are measured by liquid chromatography/tandem mass spectrometry. The cross-sectional analysis of the association between urinary paraben and biomarkers of renal function have also been established.

Results: The urinary MeP, EtP, PrP and BuP (median) levels were measured at 442, 42.9, 107 and 5.92 μg/L, respectively, which were also 10 times higher than those in other countries. Subjects aged from ≥55 to <65 yrs had higher urinary MeP and EtP levels and DI than those aged from ≥40 to <55 yrs (Fig. 1 & Fig. 2). The median of DI was higher in lotion, perfume and nail
Tubulointerstitial nephritis (TIN) in pediatrics is not always performed due to the rapid and good evolution of some patients. The diagnosis is defined by histology, but renal biopsy is typically performed only when other causes are ruled out. The causes are multiple (pharmacological 70%) and can be associated with a variety of manifestations, even with oligosymptomatic pictures, with the classic triad (fever, eosinophilia and exanthema) being observed in only 10% of cases. The most common symptom was abdominal pain (94%) and the most frequent sign was fever (94%), with prolonged febrile syndrome in 4 children. The most common symptom was abdominal pain (94%) and the most frequent sign was fever (44.4%), with prolonged febrile syndrome in 4 children. The classic triad was detected in two cases (11.1%). On admission, all patients had normal BP, with only one patient oliguric on debut. The delay from clinical onset to diagnosis was a median of 8.5 days (IQR 20.5). Renal ultrasound showed renal hyperechogenicity (25%) and associated nephromegaly (12.5%). Median eGFR at one month was 79.72 mL/min/1.73 m², with only 1 case of recurrence and 2 of chronicity. Seven cases received treatment with corticosteroids and 2 of them with immunosuppressants.

Conclusion: In every child with ARD, acute tubulointerstitial nephritis is one of the causes that we must always keep in mind in our differential diagnosis. In the series we confirm the wide forms of presentation of the disease and its various etiologies. Likewise, the evolution of the disease and the prognosis will depend on the cause and the early diagnosis, conditioning the treatment.

#2537
EPIDEMIOLOGY OF CHRONIC KIDNEY DISEASE IN THE REPUBLIC OF UZBEKISTAN

Yorkin Rasulev¹, Botir Daminov¹ and Aziz Tursunbeyev²
¹Tashkent Pediatric Medical Institute, Internal medicine, nephrology and hemodialysis, Tashkent, Uzbekistan and ²Tashkent Pediatric Medical Institute, Internal medicine, nephrology and hemodialysis, Uzbekistan

Background and Aims: Chronic kidney disease (CKD) is an emerging global health problem, currently affecting up to 15% of the global adult population, and is independently associated with an increased risk of cardiovascular disease (CVD) similar to that of diabetes mellitus or coronary artery disease. heart [Reddy K.S., Shah B., Varghese S., Ramados A. 2005; 366: 1744-1749]. To assess the epidemiological characteristics of the development of CKD in the Republic of Uzbekistan (RUz) for 2020.

Method: The object of the study is the database of the Republican Specialized Scientific and Practical Medical Center for Nephrology and Kidney Transplantation of the Republic of Uzbekistan.

Results: According to the Institute of Health and Medical Statistics of the Ministry of Health of the Republic of Uzbekistan, the number of patients with end-stage renal disease (ESRD) decreased between 2011 and 2015. However, according to the data for 2020, the number of patients with stage 5 CKD reached 23,773 thousand and its increase is expected. The proportion of patients with chronic renal failure older than 18 years was registered 21,003 thousand in 2011 and 19,149 thousand in 2015, in those years there was a decrease. However, according to the national registry for 2020, CKD cases in the Republic of Uzbekistan, identified in all regions, amounted to 118,026, there were 2,378 renal failure receiving hemodialysis - 449. The number of registered patients with CKD in the Autonomous Republic of Karakalpakstan was 9013, with CRF - 912, in need of hemodialysis - 115, receiving hemodialysis - 98, in need of transplantation - 21. In Andijan region, 416 persons were registered, with CRF - 201, in need of replacement therapy 137, receiving dialysis - 137, needing in transplantation - 11. In the Bukhara region, 4500 such patients were registered. CKD - 501, in need of substitution therapy - 172, receiving dialysis - 364 and in need of transplantation - 36.

Conclusion: With a general increase in the prevalence of CKD in the Republic of Uzbekistan in the dynamics of 2020, there is an improvement in the quality of diagnosing complications at earlier stages, at a later age and with a longer duration of CKD. Advances in the management of patients with CKD in recent years do not reduce the risk of end-stage chronic renal failure, but delay its development. Pronounced interregional differences in the frequency of registration of CKD in the database indicate problems in diagnosing CKD in a number of regions where the standard for examining patients with CKD with a mandatory assessment of glomerular filtration rate (GFR) and albuminuria at least once a year is not met.
CLINICAL FEATURES AND OUTCOMES OF COVID-19-ASSOCIATED ACUTE KIDNEY INJURY REQUIRING DIALYSIS: EXPERIENCE FROM THE FIRST COVID-19 HOSPITAL IN SERBIA

Jasna Trbojevic-Stankovic,1,2 and Zoran Marjanovic2
1Faculty of Medicine, University of Belgrade, Beograd, Serbia and 2University Hospital Center “Dr Dragisa Misovic”, Nephrology and Hemodialysis, Beograd, Serbia

Background and Aims: The new coronavirus disease (COVID-19) pandemic faced the healthcare sector worldwide with an unprecedented challenge. Although respiratory failure is the main feature of the disease, renal involvement is also common, particularly in critically ill patients, and often requires urgent dialysis treatment. This study aimed to analyse clinical features and risk factors for poor outcomes in patients with COVID-19-associated acute kidney injury (AKI) requiring dialysis. Methods: All 98 patients included in this retrospective observational study were treated in the first hospital in Serbia transformed to exclusively admit COVID-19 patients at the onset of the epidemic. Data were collected from clinical charts and patient histories for the period between March 19, 2020, and March 19, 2022, and analysed with SPSS software, version 22 (IBM Corporation, New York, USA).

Results: Out of 6,540 non-pregnant adult patients hospitalized for COVID-19 (1,955 in the intensive care unit) in the observed period, 98 (85.7% male, age range 25-89 years) developed dialysis-requiring AKI. A total of 312 hemodialyses (HD) treatments were performed (3.18±2.39, range 1-12, per patient), mostly intermittent HD (85.7% of patients) pertaining to technical resources. The majority of patients (90.8%) had at least one comorbidity – hypertension (38.8%), diabetes (28.6%), cardiovascular disease (11.2%), cerebrovascular disease (3.1%), chronic respiratory disease (7.1%), malignancy (6.1%), or autoimmune disease (1.0%). Most patients (90.8%) required mechanical ventilation. Only 8 (8.2%) were vaccinated. Nearly half (49.0%) of the patients had bilateral pneumonia and 2.0% had ARDS at presentation, with an average CT severity score of 14.65±6.72 (range 1-25) at presentation. Time to AKI presentation was 8.96±5.14 days (range 2-25). The overall mortality rate was 91.8%. Surviving patients had significantly more HD procedures performed (5.00±2.29 vs 3.02±2.23; P = .024) and significantly lower procalcitonin level (1.89±0.16 ng/mL vs 6.14±9.57 ng/mL; P = .015) at presentation. Fatal outcome was significantly more common in individuals requiring mechanical ventilation (p<0.001). Other demographic (age, sex, smoking habit), clinical (comorbidities, vaccination status, radiographic finding, CT severity score, time to AKI onset, type of dialysis) and laboratory parameters (WBC, neutrophil/lymphocyte ratio, CK, LDH, urea, creatinine, CRP, IL-6, D-dimer, ferritin) were not significantly associated with adverse outcome. Multiple logistic regression showed that fewer HD procedures were associated with patients with higher mortality rate. Higher procalcitonin, the need for mechanical ventilation and a lower number of HD procedures are significantly associated with fatal outcomes in this population.

ANCA ASSOCIATED VASCULITIS AFTER COVID-19

Dahmame Rihem, Awatef Azzabi, Raja Boukadada, Sandra Mrabet, Yosra Guedri, Sahout Wissal and Dorsaf Zellama
Sahloul Hospital, Nephrology Department, Sousse, Tunisia

Background and Aims: ANCA associated vasculitis (AAV) is a group of systemic autoimmune diseases characterized by inflammation of small and medium sized vessels. The three main types of AAV are granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA) and eosinophilic granulomatosis with polyangiitis (EGPA). Similar pathways are involved in the pathogenesis of COVID-19 and ANCA vasculitis. For instance, neutrophil extracellular traps (NETs) are induced in both entities.

Method: We describe 3 cases reports of patients with ANCA associated vasculitis after COVID19.

Results: Case 1: A 46-year-old female patient was hospitalized in intensive care unit for COVID19 pneumonia. She has fever, cough and dyspnea. A few days before, the SARS-CoV-2 polymerase chain reaction (PCR) was positive on nasopharyngeal swab. She received high flu nasal canula. She presented a pulmonary-renal syndrome with intra-alveolar hemorrhage and acute kidney injury. Chest scanner shows lesions on bilateral lung parenchyma, and an acute kidney injury (AKI) on admission. Urinalysis revealed an active sediment with dysmorphic erythrocytes and significant proteinuria. Renal function gradually deteriorated. So intermittent hemodialysis treatment was initiated. Serological evaluation showed negative antinuclear antibody, and anti-dsDNA, normal serum complements, and an elevated MPO. In kidney biopsy, pauci-immune necrotizing GN with cellular crescents was detected. The patient received pulse dose corticosteroids and subsequently, she was transitioned to oral prednisone. She underwent 2 sessions of plasmapheresis, which were stopped in the absence of confirmation of pulmonary involvement. She received cyclophosphamide during the hospitalization. While hematura and proteinuria was persistent in the most recent urinalysis, the sCr level decreased to 159 μmol/L. In addition, she developed adenral insufficiency after stopping corticosteroid therapy, requiring her to be put on Cortef.

Case 2: A 63-year-old female patient with past medical history of hypertension, was hospitalized in intensive care unit for dyspnea and hemoptysis. A few months before, the SARS-CoV-2 polymerase chain reaction (PCR) was positive on nasopharyngeal swab. She received high flu nasal canula (HFNC). At this moment, she had acute kidney injury with a sCr level of 165μmol/L that was not explored. Currently she presented a pneu-mo-renal syndrome with a rapidly progressive glomerulonephritis and intra-alveolar hemorrhage. Renal function gradually deteriorated and peak sCr level of 30μmol/L. Chest scanner shows ground glass lesions of bilateral lung parenchyma, and hemoglobin at 4.9 g/dL. Urinalysis revealed an active sediment with dysmorphic erythrocytes and significant proteinuria. Hemoptysis was not explored. Currently she presented a pneu-mo-renal syndrome with a rapidly progressive glomerulonephritis and intra-alveolar hemorrhage. Urinalysis revealed an active sediment with dysmorphic erythrocytes and significant proteinuria. Anti-neutrophil cytoplasmic antibodies (ANCA) were positive on serum from the previous patient. However, ANCA were negative on serum from the current patient. She underwent 6 sessions of plasmapheresis, for intra-alveolar hemorrhage. There was an improvement in respiratory and renal function.

Case 3: 57 years old, with a history of functional colopathy, covid infection 1 month before her hospitalization in nephrology department for kidney injury. Currently she presented a pneu-mo-renal syndrome with a rapidly progressive glomerulonephritis and intra-alveolar hemorrhage. Urinalysis revealed an active sediment with dysmorphic erythrocytes and significant proteinuria. Serological evaluation showed negative antineutrophil antibody, and anti-dsDNA, normal serum complements, and an elevated MPO. She underwent 6 sessions of plasmapheresis, for intra-alveolar hemorrhage. There was an improvement in respiratory and renal function.

Conclusion: SARS-CoV-2 infection can be a ‘trigger factor’ for vasculitis. ANCA associated vasculitis should be kept in mind in patients who develop acute kidney injury after COVID-19.
Background and Aims: Hemodialysis patients are at risk of infections due to various factors. Antibiotic resistance is an ever-changing issue. Initial empirical therapy depends on local epidemiology of infection, and antibiotic resistance pattern. Non-access related infections received lesser research attention worldwide. This study examines the spectrum of infections, and antibiotic resistance pattern.

Method: We retrospectively reviewed the records of 586 hemodialysis patients from May 2018 to April 2020 in a tertiary care hospital in North India.

Results: The study identified 99 episodes of confirmed infections. Urinary tract infections were the most common type of infections (55.5%), followed...
Uricase metabolizes uric acid into allantoin, a soluble compound that is easily excreted in the urine. Acute hyperuricemia is associated with endothelial injury and vasoconstriction, favoring acute renal failure. Preliminary studies show the protective role of lowering uric acid in cardiac patients.

Method: Pilot study conducted in patients with cardiorenal syndrome and hyperuricemia (>9 mg/dl). All received a single dose of rasburicase (0.20 mg/kg/day in the first 9 patients or a fixed dose of 6 mg in 14 patients) evaluating its effect on renal function and the need for renal replacement therapy.

Results: Twenty-three patients aged 68 ± 14 years were included, 14 men and 9 women, 87% hypertensive, 35% diabetic, 17% with liver disease, and 26% with cancer. Baseline: mean LVEF 40±14.1% (13-63), pro-BNP 19880±14000ng/L, basal Cr 1.55±0.58 mg/dl, uric acid 14±2.26, phosphorus 5 ±1.6 mg/dl and CRP 7±8 mg/L. The evolution of renal function after treatment is shown in Table 1. In all patients, uric acid after rasburicase decreased to 0.5 mg/dl. There were no differences in renal function, RRT, and hospitalization between patients who received a dose of 0.20 mg/kg/day or 6 mg iv. Only 3 patients required RRT for 21±23 hours, with recovery from acute renal failure. Comparing the patients who required RRT versus those who did not, these presented higher baseline uric acid levels: 16.5±2.5 vs 13.7±1.1 mg/dl, P = .049, and there were no differences in LVEF, pro-BNP and previous renal function. One patient died during the hospital stay due to terminal CHF and sepsis, but having recovered kidney function.

Conclusion: Rasburicase administration may prevent established renal failure in patients with cardiorenal syndrome and hyperuricemia. Early treatment, avoiding very high levels of hyperuricemia, could be more effective in reducing the need for renal replacement therapy.

ANCA ASSOCIATED VASCULITIS AND COVID

Ibolya File1, Csilla Markóth1, Reka P.Szabó1, Jozsef Balla1, László Bidiga2 and János Mátys2

1Faculty of Medicine, University of Debrecen, Hungary, Department of Internal Medicine, Debrecen, Hungary and 2Faculty of Medicine, University of Debrecen, Hungary, Department of Pathology, Debrecen, Hungary

Background and Aims: The coronavirus 2019 (COVID-19) pandemic has brought on challenges not only to acute care, but also chronic care of patients. Patients with ANCA-associated vasculitis (AAV) frequently require immunosuppression and may be at increased risk for developing COVID-19. The incidence and impact of COVID-19 in patients with AAV is currently not well known. We collected the data of patients with AAV infected with SARS-CoV-2, focused on the relationship with the employed immunosuppressants and the stage of chronic kidney disease.

Method: A retrospective study of AAV patients was conducted. Data regarding demographics, disease characteristics and therapy were confirmed by review of the electronic medical record. Information regarding current and previous therapies was collected.

Results: In our center there were 110 AAV patients who had data in the pandemic period. The majority was diagnosed with microscopic polyangiitis (MPA, n=61) or with granulomatosis with polyangiitis (GPA, n=44), there was 5 patients with eosiinophilic granulomatosis with polyangiitis (EGPA). Seventy pts (77%) were receiving immunosuppression treatment, sixteen (17.6%) of these patients employing rituximab during the pandemic period. Twelve patients on immunosuppression treatment for AAV was diagnosed with COVID infection. Eight pts had kidney transplantation, no one had positive PCR test. Thirty-two pts of the 110 pts with AAV was on chronic dialysis treatment, (29 pts on haemodialysis, 3 pts on peritoneal dialysis), eleven of them had positive PCR test for COVID-19. Among the 110 pts with AAV eighteen pts (19%) had positive PCR test for COVID-19. Seven pts had mild disease (with no or mild pneumonia), no specific therapy was applied. Five of them received immunosuppression (rituximab combined with azathioprine or micophenolate mofetil), two pts was on haemodialysis. Severe disease (dyspnea, hypoxia, or > 50 percent lung involvement on imaging within 48 hours) was reported in 7 pts. Five pts was on immunosuppression treatment (2 rituximab, 2 azathioprin, 1 leflunomide), 2 of them was on haemodialysis as well, 2 pts on HD without ISU. In the hospital four patients received favipiravir and prednisolone, no one of them died. Four pts was treated with critical disease (respiratory failure, shock, or multiorgan dysfunction). Two of them was on chronic haemodialysis, and received rituximab with azathioprine, one of them died. The other two pts was without immunosuppression, unfortunately both of them, one died. The incidence of COVID infection was higher among pts with AAV. The pts treated with immunosuppression has higher risk for COVID infection, but the mortality was not significantly higher than in other pts groups. The highest incidence of the COVID infection was in the pts on chronic dialysis treatment, mostly due to the infection during the transfer to the HD Unit.
A NEW SORBENT DEVICE FOR MULTIPLE CLINICAL PURPOSES: CURRENT EVIDENCE AT A PRIVATE HOSPITAL IN MEXICO
Jesus Mier and Ruben Merino
Sociedad Médica del Hospital Ángeles Puebla, Heroica Puebla de Zaragoza, Mexico

Background and Aims: Adsorption is an extracorporeal technique utilized for blood purification, it also complements convection and diffusion for solute removal. Since 1991, we have used blood purification techniques, over the years, new adsorption cartridges had been developed, the new ones involving treatment for inflammatory conditions, chronic uremic symptoms and autoimmune diseases. HA130, HA230, and HA330 (Jafron, Zhuhai City, China) are among the widely used adsorption cartridges in China. We report highlights of the use of hemoperfusion using HA130 cartridges in the Mexican population cohorts in the context of multiple chronic inflammatory conditions in order to support evidence of effectiveness and safety.

Method: We retrospectively analyzed the medical records of 14 critically ill patients in the context of chronic inflammatory conditions such as acute kidney injury in chronic kidney disease, acute lung injury due to SARS-COV-2 infection and sepsis. Hemoperfusion in addition to standard therapy (fluid resuscitation, vasopressors, antimicrobial therapy and ventilatory support) resulted in the improvement of inflammatory substances levels when compared to standard therapy alone. Out of the 14 patients, 7 patients used HA130 cartridges and 7 patients with standard therapy alone.

Results: There were no significant side effects associated with HA130 cartridge use. HA 130 cartridges were found to be effective in reducing uremic symptoms in chronic hemodialysis patients, improvement of pruritus score and decreased parathyroid hormone and phosphate product (p<0.05) when compared to HD alone, creatinine (MARS: −24 μmol/L, −19.5 to −10.6, p < 0.001; SPAD: −2 μmol/L, −9.0 to +7.0/L, p = 0.314) and urea (MARS: −0.9 mmol/L, −318 to −0.189, p = 0.024; SPAD: −0.1 mmol/L, −1.0 to +0.68, p = 0.523). 66.6% of cost-effectiveness when compared to standard therapy.

Conclusion: In the group of patients that used HA130 cartridges we found statistically significant (p < 0.05) reduction of pruritus score, PTH, phosphate product, creatine and urea when compared to the group of patients with standard therapy alone. The development in new cartridges technology allows more wide applications for renal patients. As we expand to involve other indications for this therapy there is cost-effectiveness improvement for the patients. More studies in different clinical settings are needed in order to achieve adsorption therapy national recommendations. We also found that the HA130 cartridges are effective in reducing uremic symptoms and microinflammatory status in acute kidney injury in chronic kidney disease patients due to the elimination of middle and small molecule uremic toxins and inflammatory mediators and endotoxins. This may translate as an improvement of quality of life and survival rates in patients with chronic hemodialysis, even though more studies are needed in order to prove this assumption.

THE URINARY BIOMARKERS IGFBP7 AND IGFBP7 X TIMP2 PRE-EMPTIVELY IDENTIFY PATIENTS AT RISK OF CONTRAST NEPHROTOXICITY
Patricia García Quintero¹, Alfredo G. Casanova¹, Javier Tascón¹, Marta Prieto¹, Moisés Pescador¹, Francisco J. Lopez-Hernandez², Ana Isabel Morales Martin¹,² and Laura Vicente-Vicente¹
¹Universidad de Salamanca, Salamanca, Spain, ²Institute for Biomedical Research of Salamanca (IBSAL), Salamanca, Spain and ³Translational Research on Renal and Cardiovascular Diseases (TRECARD), Salamanca, Spain

Background and Aims: Drug nephrotoxicity is a serious medical and economic concern. In fact, 25% of the 100 most used drugs in intensive care units are toxic to the kidney, which limits their use and, therefore, the correct therapy for the patient. The administration of contrast media (CM) during diagnostic tests or surgical interventions carries the risk of contrast-induced nephropathy (CIN), which is a clinical condition defined as an increase in plasma creatinine of 25% or 0.5 mg/dL above baseline within 3-5 days after administration. Because once instilled CM has no treatment, identification of new biomarkers predicting patients at risk of CIN before receiving CM may be crucial to prevent future kidney complications. Clinical studies conducted in other medical areas have identified new urinary biomarkers, such as insulin like growth factor binding protein 7 (IGFBP7) and tissue inhibitor of metalloproteinases 2 (TIMP2), that anticipate the risk of developing kidney damage after the administration of different potentially nephrotoxic compounds. The objective of this work was to evaluate the usefulness of these biomarkers to predict CIN in cardiac patients.

Method: A clinical study was carried out with 154 patients from the University Hospital of Salamanca Cardiology Department who subsequently received a CM. Prior to contrast administration, urine samples were collected. In addition, their plasma creatinine level was registered for the following 5 days to evaluate the development of CIN. Patients were divided into Controls (who did not develop CIN) and Cases (who developed CIN). IGFBP7 and TIMP2 biomarkers were quantified in urine samples by ELISA. Subsequently, the differences between both groups were evaluated using the Mann-Whitney U test and the diagnostic capacity of each biomarker was analyzed through the generation of its receiver operating characteristic (ROC) curve.

Results: Of the total number of patients, 123 were assigned to the Controls group and 31 to the Cases group. In both groups the distribution of sex and risk factors was similar, except for the case of age and body mass index, which was slightly lower and higher, respectively, in the Controls group. IGFBP7 was significantly higher in Cases (p < 0.01) compared to the Controls, and the IGFBP7 x TIMP2 product further improved this significance (p < 0.001). Specifically, the area under the ROC curve for IGFBP7 was 0.67 (95% confidence interval of 0.56-0.78); while that for IGFBP7 x TIMP2 increased to 0.73 (with a 95% confidence interval of 0.63-0.84). In contrast, TIMP2 alone showed no differences between both groups of patients.

Conclusion: The biomarkers IGFBP7 and IGFBP7 x TIMP2 could therefore be used for the prophylactic identification and management of patients at risk of developing CIN.

ACUTE KIDNEY INJURY (AKI) AMONG COVID-19 POSITIVE PATIENTS INCREASES THE RISK OF MORTALITY: A SINGLE CENTER EXPERIENCE
Torki Aloitaib1, Ayman Maher Nagib1,2, Nahil Alserey ³, Ahmad Abbas1, Islam Sobhy³, Prasad Nair1, Mahmoud Khalid1, Mohamed Abdelhamid1, Zohair Fayad1, Ahmed Atta1, Mohamed Mostafa1, Ahmed Yahya1, Ahmed Sami1, Mohamed Abdelmonem1, Osaam Ashary Ahmed Ghelti2,3
1OCT Kuwait, Nephrology, F, Kuwait and 2MUNC, Nephrology, Mansoura, Egypt

Background and Aims: Renal complications of COVID-19 are not yet well studied. We aimed to evaluate the prevalence of acute kidney injury (AKI) among positive COVID-19 hospitalized cases and explore its impact on patient outcomes.

Method: 586 hospitalized patients with COVID-19 were retrospectively evaluated. Of them, 267 (45.5%) developed AKI classified according to the Kidney Disease Improving Global Outcomes (KDIGO) guidelines- compared with 319 (54.5%) patients without AKI.

Results: Most cases were males (72.7% vs. 69.7%), and their ages ranged (60.8±14 vs. 51.7±16 years). Comorbid conditions significantly predominant among the AKI group were diabetes mellitus (64 vs. 42.9%), hypertension (72.6% vs. 43.5%), and ischemic heart disease (25% vs. 14.7%). Fever, cough, shortness of breath, and dehydration were the main presentations among the AKI group, and they had significant radiological findings concordant with COVID-19 (86.8% vs. 59.8%). Sepsis, volume depletion, shock, arrhythmias, and ARDS were significantly higher in the AKI group. Anticoagulation (85% vs. 59.2%), vasopressors, plasma infusions, antimicrobials, and steroids were more frequently used in the AKI group. Acute respiratory failure requiring mechanical ventilation and the overall mortality rate were significantly higher in the AKI group (62.3% vs. 32.9% and 63.2%. vs. 31.1%, respectively).

Conclusion: AKI associated with severe COVID-19 was more frequent than reports from Chinese, European, and North American cohorts. AKI risk factors included COVID-19 comorbidities like hypertension, diabetes, mechanical ventilation, male gender, and older age. Mortality was high in this population, especially elderly patients, and in those who develop KDIGO stage 3 AKI.

RISK FACTORS FOR RRT RESTART AFTER CESSATION OF CRRT: A MULTICENTER STUDY
Chungih Shin¹ and Ji Won Min²
¹Risk Factors for RRT Restart after Cessation of CRRT: A Multicenter Study, Department of Internal Medicine, Rep. of South Korea and ²Rep. of South Korea

Background and Aims: Acute Kidney Injury occurs frequently in patients admitted to the Intensive Care Unit (ICU) and continuous renal replacement therapy (CRRT) is a commonly used treatment modality in these patients. Restart of renal replacement therapy (RRT) after initial discontinuation of

Abstract
CRRT is also frequently needed. The purpose of this study is to identify clinical characteristics and biomarkers influencing the restart of RRT after the cessation of CRRT, and to build a predictive model using these parameters.

**Method:** This multicenter retrospective study includes 891 patients who were treated using CRRT from July 2012 to December 2020 in the ICU of 3 academic hospitals. The primary end point observed was the restart of RRT during hospitalization. Baseline characteristics were compared between the no restart and restart RRT groups. Using univariate analysis and logistic regression, a prospective index was developed, and receiver operator characteristic (ROC) curve analysis was performed to confirm the predictivity of the prognostic index.

**Results:** Restart of RRT was needed in 632 (71.2%) patients. Compared to patients that did not restarting, patients in the restart RRT group demonstrated higher age, higher BMI, higher baseline serum creatinine (Cr), lower urine output, longer ICU admission, and more comorbid conditions (HTN, DM, HF, ischemic heart disease). In the multivariate analysis, five parameters demonstrated independent influence on restart of RRT: HTN, Cr, ICU admission duration, BMI, and mean blood pressure. The prognostic index, which was calculated from these variables, showed a satisfactory potential to predict the restart of RRT after discontinuation of CRRT. ROC analysis revealed an area under the curve of 0.738 (95% CI, 0.703-0.773, p < 0.001).

**Conclusion:** We found that 5 of the 40 parameters observed in our study were independent risk factors for the restart of RRT during admission and we successfully developed a prognostic index based on these variables to predict the restart of RRT after discontinuation of CRRT.

**TREATMENT OF DABIGATRAN INTOXICATION IN CRITICALLY ILL PATIENTS WITH ACUTE KIDNEY INJURY: THE ROLE OF SUSTAINED LOW-EFFICIENCY DIALYSIS**

Maria Chiara Pacchiarini1, Giuseppe Regolisti2, Paolo Greco1, Tommaso Di Motta1, Giuseppe Daniele Benigno1, Marco Delsante1, Enrico Fiaccadori1 and Francesca Di Mario1

1University Hospital of Parma, Nephrology, Italy and 2University Hospital of Parma, Clinical and Medical Immunology, Italy

**Background and Aims:** Dabigatran, a direct thrombin inhibitor, is a commonly used direct oral anticoagulant (DOAC) prescribed for non-valvular atrial fibrillation. Despite its benefits in term of safety/effectiveness along with the possibility to treat patients who were ineligible for vitamin K inhibitors (VKAs), a great degree of attention is required in elderly patients with multiple comorbidities. Notably, dabigatran mainly undergoes renal elimination, and dose adjustment is recommended in patients with Chronic Kidney Disease (CKD). In this regard, the onset of an abrupt decrease of kidney function may further affect dabigatran pharmacokinetic profile, increasing the risk of acute intoxication. Idarucizumab is the approved antagonist in the case of dabigatran-associated major bleeding or concomitant need of urgent surgery, but its clinical use is limited by the lack of data in patients with Acute Kidney Injury (AKI). Given the dabigatran PK parameters (low MW, low Vd, negligible protein binding), the early start of Extracorporeal Kidney Replacement Therapy (EKRT) may represent the optimal reversal strategy. We present a case series of three critically ill patients with AKI and dabigatran overdose treated with Sustained Low-Efficiency Dialysis (SLED).

**Methods:** Three critically ill patients (Table 1) were admitted to the Renal Intensive Care Unit (ICU) for stage 3 AKI and intercurrent dabigatran intoxication. SLED sessions with Regional Citrate Anticoagulation (RCA) were prescribed with SURDIAL X machine, ELISIO-21M filter (Nipro Co., Osaka, Japan) [blood flow rate 200 mL/min, dialysis fluid rate 300 mL/min; citrate flow rate 350 mL/h (ACD Fresenius Kabi, Italia)]. Dabigatran plasma levels (dilute thrombin time, dTT) along with coagulation parameters were monitored before, during and after SLED session.

**Results:** A rapid and sustained decreased of plasma dabigatran level was observed in each patient in course of SLED sessions. No clinically relevant post-treatment rebound was reported (Figure 1).

**Conclusions:** SLED meets the requirements to be a viable reversal anticoagulation option in the context of dabigatran overdose. Indeed, it efficiently provides dabigatran removal, by reaching a safe plasma concentration within the first hours and avoiding significant rebound effect.

---

**Figure 1:** Dabigatran plasma level (ng/mL) in course of SLED session.

INTRABDOMINAL ABSCESS: AN UNEXPECTED CAUSE OF POSTPARTUM SEPSIS IN A VAGINALLY DELIVERED WOMAN WITH PREGNANCY RELATED ACUTE KIDNEY INJURY

Marwa Faisal1, Fatema Ali1, Wadiea Mansoor1, Dalia Younis1 and Rasha Samir Shemies1

1Faculty of Medicine Mansoura University, Egypt

Pregnancy related-Acute kidney injury (PR-AKI) is a life-threatening complication with substantial fetal and maternal mortality and morbidity. AKI is associated with increased risk of infection and/or sepsis. Intra-abdominal infections account for 11.9% of infections that complicate AKI among critically ill patients. The pathophysiology is not fully understood, several theories have been proposed; of which, AKI associated hypervolemia leads to tissue edema and bacterial translocation. Moreover, AKI induces a hyper-inflammatory state and suppresses the immune system, this may present a greater predisposition for infection. Here we report a rare case of intra-abdominal abscess presented in a woman with recovering PR-AKI three months following normal vaginal delivery.

Case presentation: A 20-year-old, previously healthy female patient, was admitted due to severe postpartum hemorrhage (PPH) complicating a full-term vaginal delivery. On admission, blood pressure was 170/70, heart rate was 100 beats/min, and respiratory rate was 22 breaths/min. The patient developed oliguria, generalized edema, and fever (38.5°C). The blood tests are revealed in Table I. The patient had elevated liver enzymes (SGOT, SGPT, alkaline phosphatase). Plasminogen activator inhibitor-1 (PAI-1) was also noted to be elevated, indicating an ongoing inflammatory state. CT scan imaging revealed an intraperitoneal abscess which was subsequently treated with antibiotics and percutaneous drainage.

Abstract
97 IU/L, and SGPT 117 IU/L). The patient was started on supportive treatment with packed RBC, platelet transfusion, and fresh frozen plasma. Empiric antibiotic was administered. The patient subsequently had general improvement and was discharged 17 days after delivery with partial recovery of kidney function. Three months later, the patient presented with throbbing pain in the lower abdomen and fever. Abdominal examination revealed pelvi-abdominal fullness along with mild tenderness with no guarding or rigidity. No obvious palpable lumps were detected. No abnormalities were detected in per vaginal and per rectal examinations. CT scan was performed and revealed a large sized collection in the lower abdomen sized 6.5x5x9 cm. Ultrasound guided aspiration of 60 ml pus confirmed the diagnosis of intraabdominal abscess. Intravenous antibiotics were started with percutaneous drainage of the abscess.

Discussion: Intraabdominal abscess is a serious ailment, and it is associated with high mortality and morbidity if left untreated. An intra-abdominal abscess can cause symptoms such as prolonged ileus, anorexia, fever, and abdominal pain. Septic shock may eventually develop in case of delayed treatment. However rare, there should be a causative factor. Intraabdominal abscess following a normal vaginal delivery is very rare and not reported with PR-AKI. CT scan is still the most useful technique for diagnosis and treatment. Additionally, it can help guide percutaneous drainage by locating the abscess in relation to the viscera of the abdomen. The use of adequate antimicrobial drug therapy in combination is a fundamental approach. It is therefore of great importance to consider symptoms such as atypical abdominal distension or pain in women in the postpartum period and to provide thorough comprehensive evaluation. Early diagnostic consideration greatly lessens patients' morbidity and mortality.

NON-ANESTHETIC STENTING IS AN EQUIVALENTLY EFFECTIVE METHOD COMPARED WITH PERCUTANEOUS NEPHROSTOMY IN ACHIEVING EARLY RECOVERY IN STONE INFECTED PATIENTS

Bomi Choi¹, Hoon Yu² and Sung Jin Kim³

¹Gangneung Asan Hospital, Department of Internal Medicine, University of Ulsan, College of Medicine, Gangneung, Rep. of South Korea, ²Gangneung Asan Hospital, Division of Nephrology, Department of Internal Medicine, University of Ulsan, College of Medicine, Gangneung, Rep. of South Korea and ³Gangneung Asan Hospital, Department of Urology, University of Ulsan, College of Medicine, Gangneung, Rep. of South Korea

Background and Aims: The prevalence of urinary tract stones is increasing. Although the importance of urgent decompression in managing this condition is well established, preferences for drainage methods (stenting vs. percutaneous nephrostomy [PCN]) differ depending on the treating institution. We therefore analyzed the effects of different drainage methods on early recovery.

Method: We retrospectively reviewed the medical records of patients hospitalized for infection with urinary obstruction due to urinary calculi at Gangneung Asan Hospital between January 2011 and December 2020. All patients underwent stenting or PCN. Early recovery was defined as subsided fever or discharge within 3 days after the procedure.

Results: A total of 178 patients, including 98 treated with double J stents and 80 treated with PCN were included. Univariate analysis revealed male sex, diabetes mellitus, coronary heart disease, mid ureter stone, upper ureter stone, stone size of 10-20 mm, and renal stone concomitance as significant prognostic factors for early recovery. In contrast, multivariate analysis revealed male sex, stonesize of 10-20 mm, and renal stone concomitance as significant prognostic factors for early recovery. (Table 2). When stenting was compared with PCN, the recovery period of fever and C-reactive protein and white blood cell levels showed similar trends.

Conclusion: Male patients and those without risk factors for stone-related complications tended to recover more easily after the procedure. The results demonstrate that non-anesthetic stenting is an effective method, compared with PCN, to achieve early recovery in infected patients due to stone obstruction.

EFFECT OF ORAL FLAVONOIDS ON ARTERIAL STIFFNESS IN CKD: A PILOT PROSPECTIVE STUDY

Anastasia Vagkopoulou, Nasra Haddad, Ioannis Kontogiorgos, Thomas Papatoliollis, Evaggelia Papadopoulou, Dimitrios Makridis, Stergios Tsimikas, Rigas Kalaitzidis and Despina Karasavvidou

Ptolemaida, Thesi Kouri 1, Ptolemaida, Greece

Background and Aims: Flavonoids, the main category of polyphenols possess antioxidant and antihypertensive properties mediated through endothelial protection, renin-angiotensin-aldosterone and sympathetic system suppression. The aim of the study was to evaluate the effect of oral flavonoids administration in arterial stiffness indices and of oxidative stress markers in patients with Chronic Kidney Disease (CKD).

Method: The enrolled patients received chocolate bars rich in polyphenols (200 mg) daily for a period of 3 months. The patients underwent clinical examination and laboratory test arterial stiffness measurements with SphygmoCor. Markers of oxidative stress (total phenols, total plasma antioxidant capacity, protein carbonyls) were also measured.

Results: Sixteen patients were enrolled in the study, [median age 62.5 years (± 8.2), 14 patients (87.5%) were male]. Clinical characteristics, blood pressure measurements, arterial stiffness indices and markers of oxidative stress are summarized in table 1, 2 and 3. Peripheral systolic Blood Pressure (PSBP) was decreased by 13.56 mmHg (± 2.57), (p<0.001). Pulse wave velocity (PWV) and central pulse pressure (CPP) were significantly decreased (8.2 m/sec (5.1-9.29), vs 8.85 m/sec (6.7-11.75), (p<0.001) and 47.63 (36.5-60) versus [59.13 mmHg (43.5-69 respectively) at the end of the study], (p=0.003). Markers of oxidative stress were also improved. A decreased in plasma proteinic carbonyls 52.54 nmol/ml ± 25.04 versus [73.50 nmol/ml ± 18.65, (p<0.001) was observed.

Table 1: Clinical characteristics of the study participants according to decompression procedures.

In this pilot study, oral flavonoid supplementation in the dose of 200 mg may improve arterial stiffness indices and systolic blood pressure observed while antioxidative capacity was increased 3.55% (1.15-6.38) versus 12.51% (6.26-17.66) (P = 0.013). Importantly no side effects were observed during the study period.

**Conclusion:** In this pilot study, oral flavonoid supplementation in the dose of 200 mg may improve arterial stiffness indices and systolic blood pressure measurements and contribute to the improvement of antioxidative capacity in CKD patients.

**#5569 ASSOCIATION OF URINARY CCL14 WITH PLASMA PROTEIN BIOMARKERS IN CRITICALLY ILL SEPSIS PATIENTS WITH PERSISTENT ACUTE KIDNEY INJURY**

H Peters-Sengers1,2, Thei Steenvoorden3, Lonneke van Vught1, Liffert Vogt1, Marcus Schultz4, Tom van der Poll5,6

1 Amsterdam UMC, location University of Amsterdam, CEMM (Center for Experimental and Molecular Medicine), Amsterdam, Netherlands,

2 Amsterdam UMC, location University of Amsterdam, Department of Clinical Epidemiology, Biostatistics and Bioinformatics, Amsterdam, Netherlands,

3 Amsterdam UMC, location University of Amsterdam, Department of Nephrology, Amsterdam, Netherlands,

4 Amsterdam UMC, location University of Amsterdam, Department of Intensive Care Medicine, and Laboratory of Experimental Intensive Care and Anesthesiology (L-E-I-C-A), Amsterdam, Netherlands and 5 Amsterdam UMC, location University of Amsterdam, Division of Infectious Diseases, Amsterdam, Netherlands

**Background and Aims:** The urinary concentration of CC chemokine ligand 14 (CCL14) – a chemoattractant for T-cells and monocytes – has recently been identified as a strong predictor of persistence of severe acute kidney injury (AKI). The mechanisms by which CCL14 mediates persistent severe AKI are not yet completely understood. With sepsis being the most frequent cause of AKI, we wanted to externally validate whether urinary CCL14 concentration can differentiate sepsis patients with and without persistence of AKI, and its association with plasma protein biomarkers reflective of three pathophysiologival pathways.

**Method:** Patients admitted with sepsis to the intensive care unit (ICU) were categorized according to the evolution of AKI (no-AKI, transient-AKI, and persistent-AKI, defined as lasting > 48h), and matched to a 1:1:1 ratio. AKI was assessed prospectively and daily, using the risk, injury, failure, loss, and end-stage kidney disease (RIFLE) classification. Transient- and persistent-AKI patients had at least injury or failure (severe) RIFLE stages. Urine samples collected at ICU admission were analyzed for CCL14 level; in the same patient cohort we measured 9 plasma biomarkers reflective of systemic inflammation and cytokine responses, endothelial cell activation, and loss of endothelial barrier function. We applied a recently proposed cutoff of 1.3 ng/mL for high CCL14 for the identification of patients at high risk for persistent severe AKI.

**Results:** Of 211 sepsis patients enrolled, 72 patients did not have AKI, 71 had transient AKI and 68 had persistent AKI. Majority of patients with high CCL14 had a persistent AKI (23 out of 31; 74.2%). CCL14 showed good discrimination between persistent-AKI and no-AKI (Area Under the ROC Curve [AUC], 0.82, 95%CI 0.75-0.89), and moderate discrimination between persistent-AKI and transient-AKI (AUC 0.71, 95%CI 0.55-0.87). High CCL14 was associated with lower severity scores, and source of infection being the urinary tract, and skin. The plasma protein analysis revealed that high urinary CCL14 was associated with more prominent systemic (anti-)inflammatory and cytokine responses, and signs of disrupted endothelial barrier function (shown by elevated interleukin [IL]-8 and IL-10, and decreased angiopoietin-1 [P = .005; P = .004; P = .009, respectively]). Within the persistent-AKI group, baseline characteristics (age, chronic comorbidities, and disease severity) did not differ between CCL14 groups, and high CCL14 was only associated with decreased angiopoietin-1 (P = .003).

**Conclusion:** External validation of urinary CCL14 showed good discrimination in critically ill sepsis patients between persistent AKI and no-AKI, and moderate discriminative ability to separate transient-AKI. High urinary CCL14 identifies persistent-AKI sepsis patients with more profound dysregulation of inflammatory pathways coupled with loss of endothelial barrier function. This could guide future therapeutic strategies targeting subgroups within the AKI population.
